33.11 Alfisols

C.T. Hallmark

D.P. Franzmeier

33.11.1 Introduction

The central concept of Alfisols embraces soils of the semiarid to humid climates with light-colored surfaces and subsoils moderately rich in basic cations, formed, at least in part, by movement of clay from overlying horizons into the subsoil. Most Alfisols developed under deciduous forest vegetation in humid climates and grass or savannah vegetation in drier regimes. In loamy and silty Alfisols of the humid regions, fragipans are not uncommon; in drier climates, incomplete leaching of salts and carbonates can result in concentrations of secondary carbonates, gypsum, amorphous silica, or enrichment of exchangeable Na. As the processes of formation of Alfisols require both time and energy, most are found on geomorphic surfaces that are of Pleistocene age or older. They form on a wide variety of parent materials.

In previous classification systems in the United States, most Alfisols were in the Gray–Brown Podzolic great group, but others were in the Low-Humic Gley, Noncalcic Brown, Reddish-Brown Lateritic, Reddish Brown, Reddish Chestnut, Gray Wooded and Planosol great groups. Further, natric great groups or subgroups of Alfisols also include salt-affected soils that were previously classified as Solonetz and Soloth soils (Soil Survey Staff, 1975).

33.11.2 Distribution

Alfisols occur on all continents except Antarctica (Figure 33.72). They occupy about 9.6% of the ice-free Earth's surface (Table 33.1). They are found between the latitudes of 65°N and 45°S and concentrated in the Northern Hemisphere, specifically North America, Europe, and east Central Asia between latitudes of 30°N and 65°N; also, significant occurrences are found in sub-Saharan Africa, India, South America, and Australia. Cryalfs are found within the colder reaches such as Northern Europe and into Western Russia. Ustalfs are common in sub-Saharan Africa, Eastern Brazil, the eastern portion of India, and Southeastern Australia. Udalfs are prominent in Central Europe and Eastern Australia, while Xeralfs are found in countries bordering the Mediterranean Sea.

Within the United States, Cryalfs are found in the north central states and at higher elevations in the western states. Udalfs are prominent in the eastern portion of the Midwest, along the Mississippi and Ohio River valleys while Ustalfs occur to the south and west of the Great Plains as well as the southern portion of the High Plains. Xeralfs are restricted to the west coast states.

33.11.3 Factors of Soil Formation

33.11.3.1 Parent Material

Alfisols form on a wide variety of parent materials, which includes glacial till (Borchardt et al., 1968; Smeck et al., 1968; Smith and Wilding, 1972; Ranney et al., 1975; Franzmeier et al., 1985; Weisenborn and Schaetzl, 2005), loess (Bouma et al., 1968; Grossman and Fehrenbacher, 1971), eolian sands (Davis, 1970; Allen et al., 1972; Miles and Franzmeier, 1981), residuum from limestone (Reynders, 1972), sandstone (Anderson et al., 1975; Stahnke et al., 1983; Chittleborough, 1989; Delgado et al., 1994), siltstones and shales (Gallez et al., 1975; Delgado et al., 1994), acid igneous and metamorphic rock (Goss and Allen, 1968; Ranney and Beatty, 1969; Yerima et al., 1989; Kooistra et al., 1990), mafic igneous and metamorphic rock (Gallez et al., 1975; Bhattacharyya et al., 1993; Juo and Wilding, 1996), lacustrine sediments (Borchardt et al., 1968; Ranney and Beatty, 1969), colluvium derived from acid shales and siltstones (Bailey and Avers, 1971), basalt (Weitkamp et al., 1996), coastal plain sediments (Vepraskas and Wilding, 1983; Juo and Wilding, 1996), and alluvium (Parsons et al., 1968; Ranney et al., 1975; Chittleborough et al., 1984; Klich et al., 1990; Delgado et al., 1994; Shaw et al., 2003; Calero et al., 2008). The literature is replete with examples of Alfisols developing from two or more parent materials, for example, loess over till (Allan and Hole, 1968; Foss and Rust, 1968; Ransom et al., 1987), loess over basalt (Blank and Fosberg, 1991), loess over shale (Ranney et al., 1975), loess over sandstone or limestone (Aide and Marshaus, 2002) and colluvium over residuum (Weitkamp et al., 1996). Uniformity of parent material also continues to be a question in evaluating the influence of lithogenic inherited vs. pedogenic and translocated clay in the argillic horizon (Ruhe, 1984a; Schaetzl, 1998). In eolian sands, the argillic (zone of clay accumulation) horizon usually consists of a sequence of thin bands called lamellae that contain somewhat more clay than the soil material between the bands.

Lotspeich and Coover (1962) stated that "texture of the parent material controls the texture of the soil because texture is a nearly permanent characteristic of soil," particularly in arid and semiarid regions. While this may be true in Alfisols for which the parent materials have undergone previous cycles of weathering and are rich in quartz and resistant minerals (Anderson et al., 1975), many examples are available where weathering gives rise to textures and a pedogenic mineral suite markedly different from the parent material (Paeth et al., 1971; Gallez et al., 1975).

33.11.3.2 Organisms

Most Alfisols formed primarily under hardwood forest vegetation (Soil Survey Staff, 1999), but some suborders and great groups support a significant component of grass vegetation. This is illustrated in Figure 33.73 where soil classes with abbreviated vegetative descriptions from the literature are arranged in a temperature–moisture regime matrix. Aqualfs and Udalfs support forest vegetation, although dominant species and composition of forests change in response to climatic conditions. Ustalfs and Xeralfs support moderate to dominant grassland vegetation, commonly described as savanna. The forest vegetation of moister Cryalfs yields to a greater composition of grasses as Cryalfs occupy dryer climates. It is hazardous to assume that present or presettlement vegetation (Figure 33.73) represents the native vegetation of the soil as both evolve together with climate changes over time modifying vegetative communities (Wells, 1970). Even within broad vegetative zones, individual species may influence soil properties over relatively short distances. Gersper and Holowaychuk (1970a, 1970b) showed precipitation stemflow down the trunk of American beech (*Fagus grandifolia*) trees thickened E (A2) horizons, increased low chroma mottling of B horizons, and decreased clay content, pH, exchangeable Ca, Mg, and K, CEC, base saturation, and free Fe oxides in the B horizons near the stem. Davis et al. (1995) believe available P that was correlated with microelevational changes on a cultivated Psammentic Paleustalf in Niger is related to location of bushes and trees in the savanna or to cultivation.

Fauna dwelling in Alfisols has also been credited with affecting soil formation. Nielsen and Hole (1964) found earthworm population masses of 2,218 kg ha^{-1} under a deciduous forest
FIGURE 33.73 Generalized native vegetation for selected Alfisols as a function of temperature and moisture regime. Sources are as follows: (1) Anderson et al. (1975); (2) Bailey and Avers (1971); (3) Blank and Fosberg (1991); (4) Bouma and van Schuylenborgh (1969); (5) Coventry and Williams (1984); (6) Cremeens and Mokma (1986); (7) Davis (1970); (8) Gallez et al. (1975); (9) Goss and Allen (1968); (10) Lozet and Herbillon (1971); (11) Miller et al. (1971); (12) Moberg and Esu (1991); (13) Ranney and Beatty (1969); (14) Schaetzl (1996); (15) Smith and Wilding (1972); (16) Stahnke et al. (1983); (17) Vepraskas and Wilding (1983); (18) Weitkamp et al. (1996).

and earthworm middens numbering 274,000 ha⁻¹. Essentially, all annual leaf fall was moved to the middens by earthworms. Wiecek and Messenger (1972) described calcite spheroids in acid A horizons of Hapludalfs under forest vegetation that are produced in earthworm calciferous glands and were responsible for close-range variability in soil pH of A horizons. Hugie and Passey (1963) describe burrowing activity of western cicadas, crediting them with development of cylindrical structure as they burrowed through loamy soils. Their numbers were greatly reduced on coarse- and fine-textured materials. Ant, termite, and crustacean activity have also been described (Thorp, 1949). Crayfish activity in Ochraqualfs (formally) of the Texas coast has been so intense that up to 75% of the subsoil volume comprise their krotovinas prompting the establishment of a new great group (Vermaqualfs) to accommodate these and similar soils highly modified by fauna (Vepraskas and Wilding, 1983). Arkley and Brown (1954) observed sufficient rodent activity to suggest that mima mounds in western states are the result of pocket gophers.

33.11.3.3 Climate

In the process of clay eluviation, percolating water has mobilized silicate clays in upper horizons, carried them downward in the pedon with final deposition in subsoil horizons. This occurs most readily in climates in which precipitation exceeds evapotranspiration for at least several months each year. Consequently, Alfisols occur in semiarid to humid climates. In temperate and cool climates, Alfisols tend to form a belt between the Mollisols of the grasslands and the Spodosols and Inceptisols of very humid climates (Soil Survey Staff, 1999). In warmer climates, they often lie between the Aridisols of arid regions and the Inceptisols, Ultisols, and Oxisols of warm, humid climates.

Within the Alfisol areas, several soil properties vary with climate. Early works of Jenny (1935) and Jenny and Leonard (1934) serve to broadly illustrate soil changes over long transects where gradients of temperature and precipitation exist. When crystalline rocks of similar composition and geomorphic age weather across a temperature gradient, soil clay content in the upper solum increases with mean annual temperature. Along the 11°C annual isotherm from eastern Colorado to western Missouri, they found that with increased annual precipitation, depth to free carbonates, N and clay contents increased, and pH decreased. Partitioning climatic influence over long distances is difficult at best. Climate implies both temporal and spatial fluxes in a number of parameters including temperature, precipitation, radiation, humidity, and wind speed and direction. Locally, relief, slope, and aspect can provide a microclimate somewhat

dissimilar to the broader regional climate. Cooper (1960) illustrated the role of slope aspect on microclimate in Michigan Udalfs where he found south-facing slopes had higher light intensities, maximum air temperature, evaporation rate, and soil temperature and lower soil moisture than north-facing slopes. The B horizons of soils on the southern aspect were redder and finer in texture, and sola were thinner than those of the northern exposure. Torrent and Nettleton (1979) proposed a textural index (based upon fine silt:total silt ratios) to assess chemical weathering. Using soils, primarily Udalfs and Aqualfs developed from loess along the Mississippi Valley from Minnesota to Mississippi, they related the textural index describing weathering of silts to clays with increasing mean annual temperature. Subsequently, Ruhe (1984a), utilizing a smaller data set of Hapludalfs along a similar Minnesota to Mississippi transect, interpreted the trends as sedimentation dependent. In a companion study on the same Hapludalfs, Ruhe (1984b) related the more intensive and deeper leaching of bases in the southern sector to both historic and paleoclimate differences in annual and effective precipitation.

33.11.3.4 Relief

Alfisols occur mostly on hillslopes that are of moderate gradient and are linear or convex in cross section. On steeper slopes, clay translocation is limited because the soil is very shallow or stony or because material moves downslope, resulting in Inceptisols or Entisols. In depressional areas, downward water movement might be limited, or soil organic matter (SOM) content of upper horizons is high enough for the soils to be Mollisols.

Relief is responsible for the distribution of Aqualfs in many settings where water moves to lower topographic positions either overland or by throughflow. In these lower positions, epiaquic (perched water table) or endoaquic conditions may occur. Cremeens and Mokma (1986) described soil hydrosequences in Michigan where well- and moderately well-drained Hapludalfs yielded to somewhat poorly drained Ochraqualfs (later reclassified to Endoaqualfs) and poorly drained Haplaquepts and Argiaquolls. Argillans (clay films) and parameters related to movement of clay from eluvial to illuvial zones were greatest in the better drained soils. Working with seasonally saturated Alfisols in a toposequence on the Texas Coastal Plain, Vepraskas and Wilding (1983) found soil pH generally increased as did base saturation and exchangeable Na levels from upper to lower topographic positions. Also, smectite was the predominant clay mineral in the upper sola of the soils in the lower positions while kaolinite was dominant in higher positions. Cremeens and Mokma (1986) also found smectite in the wettest sites of their study with its absence in the better drained soils. Goss and Allen (1968) found appreciable accumulation of exchangeable Na downslope in a Natrustalf and evidence of accumulation of smectite due to relief.

33.11.3.5 Time

Alfisols in areas with moderate and cool temperatures are mostly on late Pleistocene surfaces as most of these surfaces were affected by glaciation. In warmer areas, they may be on older surfaces. Usually, there has not been enough clay translocation for the soils to be classified as Alfisols on surfaces younger than late Pleistocene. On old surfaces, leaching of bases commonly has progressed to the point where the soils are classified as Ultisols instead of Alfisols.

The length of time for development of soil and specific soil properties has long been of scientific interest (Jenny, 1941). In recent years, interest in soil age has been increasing as evidenced by the growing volume of literature (Bilzi and Ciolkosz, 1977; Bockheim, 1980; Little and Ward, 1981; Meixner and Singer, 1981; Harden, 1982; Muhs, 1982; Chittleborough et al., 1984; Catt, 1991; Markewich and Pavich, 1991; Delgado et al., 1994; Shaw et al., 2003; Calero et al., 2008). Part of this renewed interest is due to application of soil interpretation to subjects of current interest such as climate change, C sequestration rates, landscape stability, and archaeology. Improved and new methodologies to directly determine soil age such as radiocarbon assay, luminescence, amino acid analysis, paleomagnetic measurement, and U–Th disequilibrium series have augmented dendrochronology and recorded historic events (mudflows, volcanic eruptions, etc.) and indirect methods of correlation of stratigraphic units. As soil (and landscape) age increases, so does the concern for significant changes in other factors of state, particularly climate and its effect on vegetation. The time required for the development of Alfisols is incumbent upon the formation of argillic and kandic horizons. Bilzi and Ciolkosz (1977) believe that 2,000–12,000 years are required to develop fragipan-like features and argillic horizons in alluvium in Pennsylvania under udic soil moisture and mesic soil temperature regimes. In northeast Iowa on earthen mounds of varying age built by Indians, Parsons et al. (1962) found that soil genesis had taken place with A horizon properties remaining relatively constant with increasing age beyond 1000 years, E horizon platy structure developing within 1000 years (maximum expression required >2500 years) and the blocky structure plus clay translocation sufficient to meet argillic horizon definitions in the B horizon occurring between 1000 and 2500 year BP. In comparison, the nearby Fayette soil (Typic Hapludalf) had developed over a 14,000 year period. In preconditioned material used by Indians to construct mounds and ridges in Louisiana, argillic horizons in Ultisols and Alfisols had developed in 5000–5400 years (Saunders et al., 1997). Shaw et al. (2003) found Alfisols on stream terrace surfaces dating to 5500 year BP in Alabama.

In the Midwest, most Alfisols are found on surfaces affected by late Wisconsinian glaciation (12,000–25,000 year BP). In the Upper Midwest, many Alfisols formed in late Wisconsinian till deposited by glacier ice, and in outwash and lacustrine deposits from the glacier when it melted. Also, much of the Midwest and the lower Mississippi Valley was blanketed with late Wisconsinian age loess that was calcareous when it was deposited. Soils formed in it are relatively high in basic cations. This loess also covered surfaces on which soils had formed previously and had been eroded. These buried soils (paleosols) were enriched with basic cations (especially Ca and Mg) that were leached from the loess and translocated downward.

TABLE 33.49   Ages of Ustalfs and Xeralfs Included in Chronosequence Studies

Soil Class	Age, Years BP	MAP (mm)	Location	Source
Typic Haploxeralf	250,000	310	California	Meixner and Singer (1981)
Typic Haploxeralf	40,000	410		Harden (1982)
Typic Haploxeralf	130,000			
Typic Haploxeralf	600,000			
Typic Natrixeralf	60–107,000	170		Muhs (1982)
Typic Natrixeralf	120–134,000			
Typic Natrixeralf	375–460,000			
Ultic Haplustalf	3,740	420	New South Wales, Australia	Chittleborough et al. (1984)
Rhodic Paleustalf	9,220			
Ultic Paleustalf	26,700			
Ultic Paleustalf	27,040			
Ultic Paleustalf	29,000			
Paleustalf	42,500	—	Victoria, Australia	Little and Ward (1981)
Paleustalf	210,000			
Paleustalf	227,000			
Paleustalf	763,000			

All soils developed from alluvium. Dating methods in the studies include amino acid, U-series, uplift rates, and stratigraphic correlations.

Alfisols of ustic and xeric soil moisture regimes and developed from alluvium have been included in a number of chronosequence studies (Table 33.49). The annual precipitation ranged from 170 to 420 mm. The youngest Alfisol (Ultic Haplustalf) was 3,740 years BP and the oldest (Paleustalf) was 763,000 years BP, while the youngest Paleustalf was 9,220 years BP. Much older Haploxeralfs were noted in the California studies, but in the xeric moisture regime sufficient development of the argillic horizon to permit classification as a Palexeralf had not occurred.

33.11.4 Morphology

The morphology of Alfisols ranges greatly across the broad spectrum of conditions under which they occur. In all Alfisols, however, there is an increase in clay content from the A and E horizons near the surface to the B horizons below. In most Alfisols, this clay increase meets the concept of an argillic horizon where the illuvial Bt (t from ton Gr, clay) horizon shows evidence of oriented clays. In older soils dominated by low activity clays (low CEC of the clay fraction), evidence of oriented clay may be absent but clay increase is sufficient for a kandic horizon.

Where some of the clay in the Bt horizon is oriented, that is, stacked like a pile of papers or playing cards, the oriented clay may be on ped surfaces where it forms clay films (thin layers of oriented clay) that often cover and may be a different color from sand grains in the ped (see Chapter 30 for electron micrograph of a clay film). In sandy soils, the oriented clay forms bridges between adjacent sand grains and may line root channels. Often, this clay mentioned above actually contains a fair amount of silt. In many Alfisols, the transitional EB or BE horizons have silt coatings instead of clay on the outside of peds. In these, and some other Alfisols, especially those formed in calcareous parent materials, the best developed clay films are in the lower Bt horizon. Apparently, clay is stripped from the ped coatings in the upper B or BE horizon and is deposited on ped surfaces deeper in the profile, illustrating that clay translocation is a dynamic process, and that the argillic horizon is moving down in the profile.

Before a soil can be classified in *Soil Taxonomy*, germane diagnostic horizons and soil properties (defined in Chapter 31) must be identified. Several are essential or common in Alfisols, and their occurrence in the various suborders of Alfisols is shown in Table 33.50.

TABLE 33.50   Occurrence of Soil Horizons or Properties in Soils of the Suborders of Alfisols

	Soil Horizon or Property									
Suborder	Argillic Horizon	Natric Horizon	Kandic Horizon	Glossic Horizon	Fragipan	Duripan	Plinthite	Very Red Argillic	Very Deep Argillic	Other
Aqualfs	X	X	X	X	X	X	X			Biotic activity, very cold[a]
Cryalfs	X			X					X	
Udalfs	X	X	X	X	X			X	X	Fe nodules
Ustalfs	X	X	X			X	X	X	X	Calcic/Petrocalcic
Xeralfs	X	X			X	X	X	X	X	Calcic/Petrocalcic

[a] Also: abrupt clay increase at upper boundary of the argillic horizon, and perched water table.

33.11.5 Suborders: Their Morphology, Distribution, and Use

The Alfisol order is subdivided into five suborders, one based on temperature and four based on soil moisture regime. Cryalfs are the Alfisols in cold climates. Of the four suborders based on soil moisture regime, three (Udalfs, Ustalfs, and Xeralfs) follow broad geographical climatic belts. The distribution of Aqualfs depends on local landscape and parent material factors. A complete listing of the great groups and subgroups in each suborder appears in Table 33.51.

33.11.5.1 Aqualfs

These are the wet Alfisols in which the water table is at or near the surface (50 cm) for at least several weeks each year, but may be very deep during the dry season. The water table may be continuous to the aquifer, or it may be held up by a layer with low permeability in or just beneath the soil surface. Their location in the landscape is controlled mainly by local conditions of parent material and relief. They occur as small areas in larger areas of Cryalfs, Udalfs, Ustalfs, Xeralfs or other soil suborders, but they are more common in zones of Udalfs than Ustalfs. They may have several kinds of diagnostic horizons (Table 33.50). Nearly all Aqualfs had forest vegetation at some time in the past (Soil Survey Staff, 1999). Most are cultivated after they were drained by underground tiles or ditches. Rice is a common crop in warmer regions.

Aqualfs display quantifiable redoximorphic features (gray colors) immediately below a depth of 25 cm from the mineral soil surface. In the absence of quantifiable redoximorphic features, a positive reaction to active Fe^{2+} (α,α-dipyridyl) can be used. In this process (gleying), soil horizons are saturated with water, microbes deplete available O_2, causing Fe(III) in brownish and reddish Fe oxide minerals to be reduced. The resulting Fe^{2+} is released into the soil solution, much of which is leached from the soil. The result is that the horizon, or much of it, takes on the gray color of the silicate minerals. Gleyed horizons are designated with a g as Btg.

Gleying in Aqualfs may be noted in the upper 25 cm of the soil. Gleyed soils are generally found on lower topographic positions receiving additional water, or on broad, level interfluves where surface drainage may be very slow. The A horizon, commonly overlain by O horizon material in varying stages of decomposition, is usually either too thin or too low in organic C to meet requirements of a mollic epipedon. A few may qualify as an umbric or mollic epipedon, but have insufficient bases in the subsoil to be classified as Mollisols. Most Aqualfs have well-developed E horizons, although the underlying Bt and Btg horizons often show only minimally expressed clay films. Boundaries between E and Bt and Btg horizons often show evidence of mixing by fauna (i.e., crayfish) or tongues and stringers of E horizon material between structural units of Bt and Btg material (glossic material).

33.11.5.2 Cryalfs

Cryalfs are restricted to frigid and cryic temperature regimes and generally occur in more mountainous and sloping landscapes that are well drained. They formed in North America,

eastern Europe, and Asia above 49°N latitude and in some high mountains of lower latitude where they occur at lower altitudes than Spodosols or Inceptisols. Most have been under coniferous forest because of the cool, short growing season. Commonly, parent materials are residuum or colluvium from local bedrock. Most are not cultivated, and thus, have thin to moderately thick (2–10 cm) O horizons in varying stages of organic matter decomposition. Many lack A horizons, but when present, they are thin (5 cm) with granular or subangular blocky structure. Most have E horizons of platy or subangular blocky structure that are relatively thick (15–30 cm). The Bt horizons range from thin to thick (15–135 cm), display a wide range of clay film features, and commonly have angular or subangular blocky structure. Many have lithic or paralithic contacts, and most contain significant quantities of coarse fragments throughout the solum.

33.11.5.3 Udalfs

These are the freely drained Alfisols of humid regions, extensive in the United States and Europe. They formed under forest vegetation at some time during their development. The forests were mainly deciduous, but in colder regions, may have been mixed coniferous and deciduous. Many Udalfs have been cleared and intensively farmed; in some that have been severely eroded, the Bt horizon is immediately below or may be incorporated into the Ap horizon (Soil Survey Staff, 1999). Many have fragipans, and some have natric and other diagnostic horizons (Table 33.50). Corn and soybeans are common crops on Udalfs.

In well-drained, temperate humid environs under forest, uncultivated Udalfs have thin (2–5 cm) O horizons with organic matter in various stages of decomposition. Most also have a thin (10–15 cm) A horizon commonly of granular structure darkened by organic matter and underlain by a thin (10–15 cm), light-colored E horizon with platy structure, a zone of maximum eluviation of silicate clays. Because many Alfisols are cultivated, the A and E horizons have been mixed by plowing producing a light color. The intense eluviation in E horizons results in a concentration of sand and silt, and in extreme cases, all or most coloring compounds have been removed leaving skeletal grains whose color dominates the horizon. Often there is a transitional EB or BE horizon between the E and Bt horizons. As compared with the thinner A and E horizons, the Bt horizon is thick, possesses subangular or angular blocky structure, and contains significantly more silicate clay. At least a portion of the silicate clay occurs as clay films on structural or pore surfaces. In the Midwest where most of the parent material is calcareous and associated with the last glaciation, complete leaching of carbonates from the solum has occurred while C horizons remain calcareous.

33.11.5.4 Ustalfs

These are the Alfisols of subhumid to semiarid regions. Moisture moves through these soils to deeper layers only in occasional years (Soil Survey Staff, 1999). If there are carbonates in the parent material or in dust, the soil may have a carbonate-enriched horizon (calcic) below the argillic. Original vegetation may have been xerophytic trees, savanna, or grassland. Dryland crops for

Ustalfs include drought tolerant selections such as sorghum, wheat, cotton, and millet. Ustalfs, which are common in the southern Great Plains, do not have fragipans, but may have several other kinds of diagnostic horizons Table 33.50.

In the United States, Ustalfs tend to be on older landforms than Udalfs and have thicker sola; many are in the Paleustalf great group because of either an abrupt textural change between E and Bt horizons or a thick Bt horizon enriched in clay throughout. There is less tendency for E horizons to display platy structure, while with less rainfall, E horizons are often absent. The Bt horizons often have prismatic parting to angular or subangular blocky structure. Secondary carbonates commonly accumulate to form calcic horizons in the lower portion of the argillic horizon or just below it in the dryer Ustalfs.

33.11.5.5 Xeralfs

These occur in regions that have a Mediterranean climate, where precipitation occurs during the cool season and the summers are hot and dry. In some winters, water moves through the entire soil profile to deeper layers. Most Xeralfs border the Mediterranean Sea or lie to the east of an ocean, such as those in the western United States and Australia. Where there is no irrigation, grains are common crops but with irrigation, a variety of crops can be grown. Grapes and olives are grown in the warmer areas (Soil Survey Staff, 1999). Occurrence of E horizons is uncommon, and A horizons with weak subangular blocky structure to massive condition tend to range from 15 to 25 cm thick. Most argillic horizons are relatively thin (15–75 cm) with significant quantities of coarse fragments throughout the pedon.

33.11.6 Soil Formation Processes

33.11.6.1 Clay Translocation

Alfisols and Ultisols form mainly by eluviation of silicate clay from A and E to Bt horizons. In Alfisols, however, the base saturation of deep subsoil layers is greater than it is in Ultisols. Alfisols are similar to the Gray–Brown Podzolic soils of previous soil classification systems. The name Alfisol was derived from the term Pedalfer, a coined word used in previous classifications derived from ped, as in pedology (the science of natural soils), Al, aluminum, and Fe, iron. The implication is that in Pedalfers, Al and Fe accumulate in the subsoil, in contrast to Pedocals, in which Ca accumulates.

The concept of Gray–Brown Podzolic soils originated at a time when soil colloids (clays) were thought to be mainly amorphous. Then, soil scientists determined total chemical composition of the colloidal fraction and interpreted the results by examining SiO_2/Al_2O_3 and $SiO_2/(Fe_2O_3 + Al_2O_3)$ ratios of the various horizons. These ratios showed that both Podzols (Spodosols) and Gray–Brown Podzolic soils had B horizons enriched in Fe and Al, but that Podzol B horizons were also enriched in organic C. This led Marbut (1935) to conclude that the differences in the processes leading to the two kinds of soil were of degree, not kind, and that Gray–Brown Podzolic soils were less developed than Podzols. The word Podzolic is a descriptor previously used for many Alfisols.

Hendricks and Fry (1930) reported two key discoveries that laid the groundwork for the current understanding of the processes by which Alfisols form. First, they showed that soil colloids are mainly crystalline silicate minerals, and that when clay suspensions are allowed to dry, the plate-shaped minerals lay flat to form masses that have a regular crystallographic, or at least optical, arrangement and are large enough to study with a polarizing microscope. This discovery led to an understanding that in Alfisols, the material translocated is mainly silicate clay minerals (with Fe oxides on their surfaces), but in Spodosols, it is mainly amorphous complexes of organic matter with Al and usually Fe. Second, they provided the basis for interpreting what are now called clay films.

These ideas were gradually applied to studies of soil genesis. Jenny and Smith (1935) produced early stages of argillic horizon formation in columns of pure quartz sand by first coating the sand grains with electropositive iron hydroxide and then passing dispersed clay through the column. Brown and Thorp (1942) noted that the B horizons in the Miami soil (Hapludalf) from Indiana and similar soils contained much more clay than did the A and E horizons. They concluded, however, that the clay increase in the B horizons was only partly due to illuviation. Although the types of clay were identified by x-ray diffraction and thermal methods, soil formation processes were still discussed mainly in terms of $SiO_2/(Fe_2O_3 + Al_2O_3)$ ratios. Frei and Cline (1949) concluded that the apparent loss of clay from A and E horizons and the apparent gain in clay in B horizons of a New York soil could be accounted for in at least three possible ways: (1) clay migrates downward as a sol in percolating water; (2) clay is synthesized in the B horizon from soluble weathering products that were released there or moved down in the profile; or (3) the apparent increase in clay was really due to loss of other materials, such as $CaCO_3$. They showed, too, that there was a strong concentration of clays with a high degree of optical continuity on peds in the B horizon of a Gray–Brown Podzolic soil, but in the upper B horizon, these coatings were highly degraded. According to their interpretation, clay that was mobilized in A and E horizons and stripped from ped surfaces in the upper B horizon, moved down the profile in suspension, and was deposited on ped surfaces as films of oriented clay particles. Thorp et al. (1959), in another study of the Miami soil of Indiana, showed that the small particle size of clays, their association with organic compounds, and shrink/swell cycles in upper horizons all enhanced their mobility.

In summary, the movement of clay from A and E horizons to Bt horizons can be viewed as the net result of three subprocesses: dispersion, transport, and deposition (Jenny, 1980). Dispersion, the release of individual clay particles from aggregates, is favored by the replacement of exchangeable Ca^{2+} with Na^+, by adsorption of humus molecules on clay particles, and by mechanical disruption of aggregates, which may be caused by wetting and drying, freezing and thawing, or by mechanical disruption by faunal activity. Small particles move more readily than large particles, so that illuvial clay, as in clay films, contains more fine than immobile clay, such as that in ped interiors. Little clay is dispersed in calcareous soil materials because Ca^{2+} ions on exchange sites favor clay flocculation. Clay that is mobilized in A and E horizons

moves as a percolating sol or as slurry creep along ped surfaces. Deposition is favored when Na$^+$ is replaced by Ca^{2+}, resulting in clay flocculation by an increase in pH, or by reaction of the silicate clay with oxides such as Fe oxide. When the water of a slurry enters into a ped, the clay it contains is deposited on the ped surface, like passing the slurry through filter paper. In some cases, the slurry moves down to the wetting front in the subsoil, and clay is deposited as water evaporates or is taken up by plants. Texture discontinuities may also arrest the percolation of suspensions.

Because many Alfisols formed in calcareous materials, CaCO$_3$ must be dissolved and the weathering products leached from the soil before much clay can move. Usually H$^+$ replaces a portion of the Ca^{2+} in these Alfisols, causing leached horizons to become acidic. The shallowest depth at which carbonate minerals are found, as detected by dilute HCl, serves as an index of the intensity and length of soil formation.

It should be stressed that although illuviation of clays is diagnostic for the argillic horizon, much or even most clay in the Alfisol Bt horizons originates from other sources to include inheritance from parent material, clay neoformation, in situ weathering of lithogenic minerals, and dissolution of silt- and sand-sized carbonates (Smeck and Wilding, 1980).

33.11.6.2 Natric Horizons

Natric horizons are argillic horizons high in exchangeable Na$^+$. A natric horizon in an Alfisol seems to be an oxymoron; if rainfall has been high enough to move sufficient clay for the horizon to qualify as an argillic horizon, Na$^+$ should have long since been leached from the soil. However, natric horizons do exist in Alfisols indicating that there are circumstances in which they form. Some might be caused by a change in climate where the argillic horizon was formed during a previous wetter period, but rainfall is now less, and the leaching of Na$^+$ is reduced. Other soils with natric horizons occur in small areas where Na$^+$ has accumulated. Although the original source of much of the Na is feldspar minerals, Na$^+$ moves about in the landscape once it is released into solution. Often, soils with natric horizons are low in the landscape because solutions containing Na$^+$ move downslope either on the soil surface or through subsurface horizons, thus concentrating Na$^+$ in the low areas. In some soils, Na$^+$ is retained in the soil because the hydraulic conductivity of B horizons is very low, and leaching of Na$^+$ is retarded. This seems to be a self-perpetuating process; Na$^+$ accumulates because permeability is low, while Na$^+$ promotes dispersion, further slowing permeability. Furthermore, some soils with natric horizons were formerly saline soils. When soluble salts are leached from a soil, Na$^+$ may remain behind on the exchange sites.

33.11.6.3 Fragipan Formation

Fragipans occur in many Alfisols of the humid temperate regions, especially those of silty and loamy textures. These subsurface horizons restrict the entry of water and roots into the soil matrix (prisms) and often underlie argillic horizons. Commonly, the fragipan has a relatively low content of organic matter and high bulk density relative to horizons above. Most fragipans consist

1. Root
2. Humic matter
3. Non-bleached earth
4. Bleached earth
5. Iron precipitation
6. Clay accumulation, diffuse or compact (black)
7. Platy or lenticular structure
FIGURE 33.74 Schematic of a fragipan in an imperfectly drained silty soil. (Reprinted from van Vliet, B., and R. Langohr. 1981. Correlation between fragipans and permafrost with special reference to silty deposits in Belgium and northern France. Catena 8:137–154. Copyright with permission from Elsevier Science.)

of prisms more than 10 cm across with light-colored coatings on prism faces. These light-colored coatings form a polygonal pattern as shown in Figure 33.74. Material within prisms has brittle failure, a tendency for a clod to rupture suddenly rather than undergo slow deformation when pressure is applied. Fragments of the fragipan slake (fall apart) when submersed in water.

There are many theories on how fragipans form, summarized in two reviews (Smalley and Davin, 1982; Smeck and Ciolkosz, 1989). One reason for the diversity in ideas is that there may be several kinds of horizons included under the name fragipan, each with its own set of processes of formation. Most soil scientists believe that they have formed, or are forming, under present day conditions. The main evidence that fragipans are genetic horizons related to the current land surface is that they are roughly parallel to the soil surface, and the upper boundary has a relatively narrow range of about 50–100 cm depth. Some scientists, however, believe that they formed much earlier. The following are some of the various theories of fragipan formation.

33.11.6.3.1 Paleosols

According to this theory, fragipans formed in earlier times and were buried by younger deposits in which fragipans are not forming. In western Tennessee, Buntley et al. (1977) observed that fragipans are mainly in older loess deposits that were buried by younger Peorian loess in which no fragipans form.

33.11.6.3.2 Rapid Initial Development

Some workers believe that fragipans formed quickly in their life history. Fragipan formation has been related to periglacial

conditions (Payton, 1992) and to permafrost (FitzPatrick, 1956; van Vliet and Langohr, 1981). The polygonal pattern formed by coatings on the coarse prismatic structure is similar to that found in periglacial regions. Others present evidence that the structure of loess collapses when it first dries after deposition (Bryant, 1989), and that this denser material becomes the fragipan.

Much glacial till is very dense because it was compacted by the mass of glacier ice. Subsoil horizons that form in dense till may inherit some of their strength from the parent material (Lindbo and Veneman, 1989), but they might also develop fragipan properties through soil-forming processes. In these soils, which are common from eastern Ohio to New England, it is difficult to decide whether the dense material should be considered a fragipan or a slightly modified parent material. The great strength of these horizons is due in part to their high density, but it may also be due to cementation by Si or carbonates (McBurnett and Franzmeier, 1997). The Cd horizon was introduced, in part, to describe little altered, unconsolidated, dense till which exclude roots much like fragipans (Soil Survey Staff, 2006).

33.11.6.3.3 Chemical Cementation

Fragipans could also be cemented by Fe-, Al-, or Si-rich materials. Iron-rich materials cause the cementation of ortstein layers, and silica bonds particles together to form duripans. Although duripans form mainly in aridic and xeric climates, in more humid climates, they grade into fragipans (Soil Survey Staff, 1999). The idea that fragipans are cemented by silica was first proposed in the 1930s and 1940s but was discredited and ignored for about 40 years before revitalized in the late 1970s. The proposal requires certain interactions of parent materials and climate (Franzmeier et al., 1989). In addition to undergoing periodic leaching, soils must also become seasonally dry, which commonly occurs in areas with a udic moisture regime under hardwood forest. Also, downward percolation of soil solutions must be arrested, rather than passing quickly through subsoil layers. This could be caused by the depth of penetration of the wetting front, by discontinuities in parent materials (Smeck et al., 1989), or by slowly permeable, deeper subsoil layers. Silicate minerals weather in upper horizons, and the silica released moves down, usually in the winter and early spring, to the subsoil where it remains for a time. When the trees leaf out, water taken up by roots concentrates silica in solution eventually causing it to precipitate. Compared with grasses, hardwood trees take up relatively little Si, and thus have the potential to concentrate Si in the soil. The precipitated silica bridges between clay particles, or more likely between Fe oxide minerals adsorbed on silicate clay surfaces, causing weak cementation. The greater Si uptake in grasses may be the reason that fragipans do not form under prairie vegetation in humid climates (Franzmeier et al., 1989). The precipitation of Si must be somewhat irreversible, or else any cementation that formed in the summer would be destroyed in the winter, and no net fragipan formation would take place. Fragipans do not form readily on steep slopes, in deep loess, or in loess over more permeable materials, such as outwash. In these soils, the soil solution moves laterally

downslope or through the profile, preventing the accumulation of Si-rich soil solutions.

Most of these theories of fragipan formation individually have deficiencies. Perhaps, various combinations of them can explain how a particular soil forms.

33.11.7 Selected Physical, Chemical, and Mineralogical Properties

An increase in clay content between the E and/or A horizon(s) and underlying Bt horizons occurs in all Alfisols; however, this textural contrast ranges from little to great. This is illustrated (Figure 33.75) by the change in clay content with depth for a Psammentic Haploxeralf from California (Torrent et al., 1980), a Typic Hapludalf from Illinois (Grossman and Fehrenbacher, 1971) and a Udertic Paleustalf from Texas (Klich et al., 1990). The Psammentic Haploxeralf has a minimal argillic horizon, with a clay increase of about 4% above that of eluvial horizons. By contrast, the Paleustalf shows a clay increase of more than 40% between the surface horizon and the finest textured portion of the argillic horizon. The Hapludalf is intermediate in textural contrast.

Alfisols with Bt horizons dominated by fine clay (<0.0002 mm, usually smectitic) display significant volume change between wet and dry states. This volume change is reported as the coefficient of linear extensibility (COLE) and can be determined from bulk density values associated with moist and dry, natural clods
FIGURE 33.75 Clay distribution in three Alfisols of contrasting degrees of argillic horizon development. (From Torrent, J., W.D. Nettleton, and G. Borst. 1980. t, trace; Ch, chlorite; Ve, vermiculite; ln, interstratified 2:1 minerals; Sm, smectite; Mi, hydrous mica or illite; Ka, kaolinite; Qz, quartz; GH, goethite and/or hematite; Ps, pseudomorphs of clay minerals; Kf, K feldspar; Pl, plagioclase feldspar; Mi, mica; Qz, quartz; Vg, volcanic glass; AP, amphibole and/or pyroxene; Ze, zeolite; a, abundant; c, common; t, trace; +, chloritized vermiculite also noted.

[a] Relative amounts 3 = >50%; 2 = 10%–50%; 1 = <10%.

[b] Values are for a major fraction of sand or slit.

(Grossman et al., 1968). The Paleustalf in Figure 33.75 has COLE values >0.07 (7% volume change between moist and dry states) for horizons containing 30% or more clay. Because such soils are intergrades to Vertisols and possess similar features such as high subsoil clay content and shrink/swell potential, and slickensides, they present similar problems for use as construction materials (i.e., unstable subgrades for roads and houses).

Texture and clay content affect water-holding and water transmission properties of soils since water-related properties are dependent on void size and continuity. When the size of voids change greatly over a short distance, water movement is restricted. Alfisols with lamella type argillic horizons may exhibit slower drainage and better soil–plant relations due to greater available water retention than similar textured soils without lamella. Under more extreme conditions, strongly contrasting textures of eluvial and argillic horizons may result in water perched above the argillic horizons for several weeks as in Natraqualfs and Albaqualfs. In Alfisols with compact, clayey argillic horizons, root growth may be limited primarily to structural planes due to the high bulk density of ped interiors. Jones (1983) showed that root exclusion due to soil bulk density is a function of clay content.

Although organic C is greatest in the surface horizons, Alfisols tend to have greater CEC in the argillic horizon where clay and smectite contents are greatest. Generally, Alfisols must have a base saturation of 35% or more at the shallower of the following depths: (1) 1.25 m below the top of the argillic or kandic horizon, (2) 1.8 m below the soil surface, (3) 75 cm below the top of a fragipan, or (4) immediately above a densic, petroferric, lithic, or paralithic contact (just above continuous hard or soft bedrock; see Soil Survey Staff, 2010, for details). Most Alfisols have base saturation percentages well above 35%; those that approach low base status are recognized as intergrades to Ultisols by classification in Ultic subgroups. Generally, base saturation (and pH) decreases initially with depth in Alfisols, often reaching a minimum in the E horizons or upper portions of the argillic horizon, then increases again with depth. Alfisols under deciduous forest vegetation have relatively high base saturations in the surface horizon due to cycling of basic cations from depth to the surface in leaf fall. The relationship between soil pH and base saturation (Beery and Wilding, 1971; Blosser and Jenny, 1971; Ranney et al., 1974) is often used in field operations to separate Alfisols from Ultisols, but care must be exercised as this relationship changes with mineralogy.

The mineralogy from a range of Alfisols illustrating variations in parent materials, climates, and degree of development is presented in Table 33.52. Most Alfisols contain substantial quantities of 2:1 clay minerals such as smectite and hydrous mica, and perhaps some vermiculite, chlorite, and kaolinite. However, for more intensely weathered Alfisols (Kandiudalf, Paleudalf, Paleustalf, and Plinthustalf), kaolinite is the dominant clay mineral in the argillic or kandic horizon. Similarly, the most common mineral dominating the sand and silt fraction is quartz (Table 33.52), which comprised >90% of the sand fraction in the Paleustalf and Paleudalf. The Udalf from Oregon, which formed from tuff and breccia, was dominated by plagioclase feldspars.

Most Alfisols contain significant quantities of weatherable minerals including K feldspars, plagioclase, and mica in the sand and silt fractions.

33.12 Ultisols

Larry T. West

Joey N. Shaw

Fredrich H. Beinroth

33.12.1 Introduction

Ultisols are a group of soils with an argillic or kandic horizon and low base saturation in lower subsoil horizons. These soils may be found on a variety of parent materials and under a range of climatic conditions, though most have developed under forest vegetation in humid climates. Ultisols are generally considered to be less productive than soils in many of the other orders, but in many regions of the world, they are the most productive soils available. With proper management of organic residues, fallow periods, and/or chemical inputs, the productivity of this resource can be enhanced and maintained. This section presents a brief overview of Ultisol genesis and properties. For a more comprehensive review, the reader is referred to Miller (1983) and West et al. (1997).

33.12.2 Classification: Historical and Current

As soil classification has evolved in the United States, soils currently considered to be Ultisols have been included with the Red soils, Yellow soils, or Lateritic soils (Marbut, 1928), the Yellow Podzolic or Red Podzolic great soil groups (Baldwin et al., 1938), and the Red–Yellow podzolic great soil group (Kellogg, 1949). The order Ultisols was introduced in the *7th Approximation* (Soil Survey Staff, 1960) to include soils with an argillic horizon and base saturation <35% in lower subsoil horizons. The 35% base saturation criteria was placed to separate soils where basic cations are maintained in the root zone through biocycling, and soil amendments are commonly needed for sustained productivity (Ultisols), from soils that replenish a significant amount of basic cations through weathering (Alfisols) (Forbes, 1986). Since first publication of *Soil Taxonomy* (Soil Survey Staff, 1975), the classification of Ultisols has been revised to include kandic horizons as criteria for placement in the order and to include soils in any temperature regime. For a comprehensive definition of Ultisols, the reader is referred to the *Keys to Soil Taxonomy* (Soil Survey Staff, 2010). Table 33.53 lists current orders, suborders, and great groups in Ultisols (Soil Survey Staff, 2010).

33.12.3 Geographic Distribution

Worldwide, Ultisols are currently estimated to cover about 11,054,000 km² which is 8.1% of the ice-free global landmass (Table 33.53; Figure 33.76). About 80% of Ultisols are in tropical regions, and about 18% of the tropics is covered by Ultisols (Eswaran, 1993). About 50% of Ultisols are Udults, 35% Ustults, and 12% Aquults with Humults and Xerults comprising the

TABLE 33.53   Listing of Suborders, Great Groups and Subgroups in the Ultisols Order

Suborder	Great Group	Subgroup
Aquults	Plinthaquults	Kandic, Typic
	Fragiaquults	Aerie Plinthic, Umbric, Typic

remaining 3% (Table 33.53). In the United States, Ultisols cover about 860,000 km² (Table 33.54) and occur in 30 states and Puerto Rico (Figure 33.77). The largest concentration of Ultisols in the United States is in the east central, southeast, and south central parts of the country. Ultisols are also extensive on the older islands of Hawaii, along the west coast, and in unglaciated regions of the northeast and north central parts of the country.

33.12.4 Genesis of Ultisols

Soil as an independent natural body whose properties are a function of five soil-forming factors: local climate, parent materials, organisms, relief, and age (Dokuchaev, 1883; Jenny, 1941), is a unifying philosophy in pedology. As such, Ultisol genesis will be briefly discussed in terms of these factors.

33.12.4.1 Climate

The definition of Ultisols implies two rainfall/evapotranspiration conditions. First, there must be some time during the year when evapotranspiration exceeds precipitation, as this appears to be a prerequisite for the formation of an argillic horizon (van Wambeke, 1991). Second, precipitation must exceed the capacity of the soil to retain water during some time of the year, so that water percolates through the solum to remove basic cations and maintain low base saturation (<35% by sum of cations [pH 8.2] which corresponds roughly to 50% base saturation measured at pH 7.0) in the subsoil (Miller, 1983). Most Ultisols occur in regions with mean annual air temperatures above 6°C. Thus, the climate conducive to the formation of Ultisols is typically humid tropical or warm temperate. As many Ultisols have evolved over long time periods, effects of paleoclimate on Ultisol development cannot be ignored.

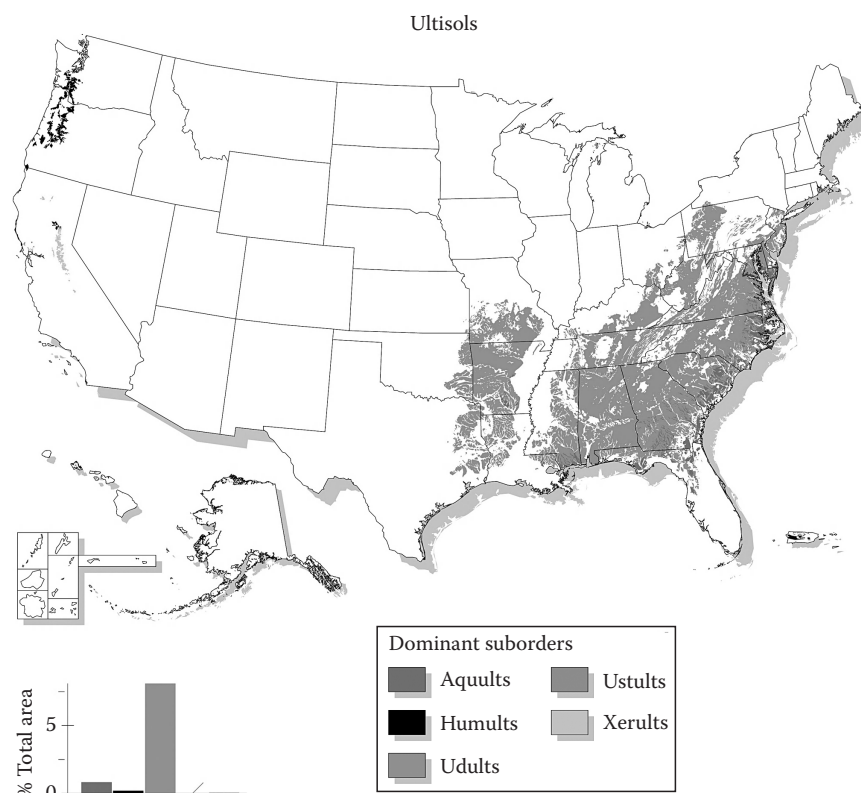
33.12.4.2 Parent Material

The definition of Ultisols requires the presence of either an argillic or a kandic horizon, both of which contain silicate clays. Therefore, the parent material of Ultisols must be one that contains either phyllosilicates or primary minerals that can weather to produce them. As the vast majority of rocks meet one or both of these criteria, a wide variety of geologic formations are capable of producing parent materials suitable for Ultisol formation. Residual parent materials that have weathered in situ are usually saprolite. In contrast, transported sediments that form Ultisol parent materials have frequently been preweathered and may have gone through more than one weathering cycle (Fiskell and Perkins, 1970; Allen and Fanning, 1983). In sedimentary landscapes, parent material has a major influence on Ultisol property distribution (Shaw et al., 2004).

33.12.4.3 Biota

Although Ultisols occur within many tropical and subtropical managed ecosystems, forests are the dominant vegetation on most natural Ultisol landscapes. The processes in forest soils appear to accelerate the formation of argillic horizons through the desiccating effect of tree roots that absorb water, but not colloids in suspension. In Africa and South America, vast areas of Ultisols are under savanna vegetation. It cannot be ascertained, however, whether the soils formed under the present vegetation or under forests in one or more humid paleoclimates.

33.12.4.4 Relief

Ultisols occur on almost all landforms. The one characteristic that Ultisol landforms have in common, however, is geomorphic stability over long periods of time. Geomorphic studies of tropical landscapes invariably show that Ultisols occupy geomorphic positions that are younger and less stable than the surfaces where Oxisols occur, but older and more stable than those of soils in other Orders with which they are geographically associated (Beinroth et al., 1974; Lepsch and Buol, 1974; Beinroth, 1981). In temperate regions where Oxisols are absent, Ultisols


Ultisols

FIGURE 33.77 Distribution of Ultisols in the United States. (Courtesy of USDA-NRCS, Soil Survey Division, National Soil Survey Center, Washington, DC, 2010.)

have developed on the oldest, most stable and highly weathered landscapes such as the central Missouri Ozarks and the coastal plain of the southeastern United States (Scrivner et al., 1966; Daniels et al., 1971).

33.12.4.5 Time

The time required for the formation of Ultisols depends on the other pedogenic factors, notably weatherability, composition, and permeability of the parent materials, landscape stability, and climate fluctuations over time. There is much room for variability in these conditions, and consequently, for the age of Ultisols. The Soil Survey Staff (1999) concluded that formation of the argillic horizon ordinarily requires a few thousand years. This relatively short time may suffice to produce a minimal expression of an argillic horizon. The development of the thick argillic horizons that typify the Pale and Kandi great groups of Ultisols, however, would certainly take longer. As such, age of Ultisols has been reported to range from <12,000 years for soils on preweathered sediments to >15 million years on marine sediments in the coastal plain of the southeast United States (Gamble et al., 1970; Daniels et al., 1971; Miller, 1983).

33.12.5 Morphological Properties

33.12.5.1 Argillic and Kandic Horizons

Other than low base saturation, the one property that distinguishes Ultisols from all but one other soil order (Alfisols,

Section 33.11) is the requirement of a clay increase between surface and subsoil horizons in the form of either an argillic or kandic horizon. This clay increase essentially determines the morphology of Ultisols and influences many chemical and physical properties. The depth, thickness, and clay content of the argillic or kandic horizon, however, can vary widely, and this variation has considerable impact on management and interpretation of these soils. Figure 33.78 illustrates the range in depth and clay content of argillic or kandic horizons that can occur in Ultisols.

33.12.5.2 Soil Color

Color of surface horizons in Ultisols is commonly brown, yellowish brown, dark brown, or red as would be expected for soils with relatively low amounts of soil organic C (SOC). However, in cool climates or poorly drained conditions with slow organic matter decomposition, thick, dark, acidic surface horizons (umbric epipedons) are common. Many well-drained Ultisols have reddish Bt horizons because of the presence of hematite as a pigmenting agent. Yellowish-brown subsoil horizons, also common in Ultisols, lack hematite because either the parent material lacked mineral precursors for hematite, environmental conditions precluded hematite formation (Schwertmann and Taylor, 1989), or hematite was preferentially reduced and lost under short periods of saturation leaving behind more stable goethite (Macedo and Bryant, 1989; Dobos et al., 1990). Under extended periods of saturation and reduction, Ultisols will develop redox

FIGURE 33.78 Clay distribution with depth for four subgroups of Ultisols.

concentrations and depletions or gray matrices as Fe is reduced and mobilized.

33.12.5.3 Plinthite

Plinthite is defined in *Soil Taxonomy* as an Fe-rich, humus-poor mixture of clay with quartz and other diluents (Soil Survey Staff, 2010). This material most often occurs in lower subsoil horizons, is weakly indurated, and is normally low in basic cations and primary silicate minerals other than quartz. Kaolinite is commonly the only clay mineral present with abundance. The reader is referred to van Wambeke (1991) for a complete discussion of the genesis and kinds of plinthite and petroplinthite (or ironstone).

From a pedological perspective, plinthite's relationship with contemporary soil saturation is not well understood, but it does have significance in terms of movement of water through soils. Daniels et al. (1978) suggested that 10% platy plinthite would perch water. A similar amount of nodular plinthite was not considered to be water restrictive, but horizons subjacent to the plinthic horizon did restrict water movement. Movement of water and solutes through horizons containing plinthite is primarily restricted to areas of redox depletions (Carlan et al., 1985; Blume et al., 1987; Shaw et al., 1998). Because of water perching by plinthic or subjacent horizons, plinthite in soils suggests that water and solutes are moving from high to low landscape positions as shallow subsurface flow (Hubbard and Sheridan, 1983; Shirmohammadi et al., 1984).

33.12.6 Mineralogical Properties

33.12.6.1 Clay Minerals

The clay fraction of subsoil horizons of most Ultisols is dominated by kaolinite because of the stability of kaolinite when compared with other phyllosilicates (Jackson et al., 1948; Allen and Fanning, 1983). In addition, gibbsite, K mica, K feldspar, and amorphous silica may transform directly to kaolinite without passing through intermediates (Garrels and Christ, 1965). As such, kaolinite in soils has been shown to be an early weathering product of biotite and K feldspar in acid gneiss and schist parent materials (Robertus and Buol, 1985; Robertus et al., 1986; Norfleet and Smith, 1989).

In addition to kaolinite, hydroxy Al-interlayered vermiculite is often abundant in A and E horizons of Ultisols and may be a major component of upper Bt horizons of these soils (Bryant and Dixon, 1964; Fiskell and Perkins, 1970; Carlisle and Zelazny, 1973; Harris et al., 1980; Karathanasis et al., 1983). Studies in the Piedmont and Coastal Plain of Alabama (southeastern United States) indicate that hydroxy Al-interlayered vermiculite is more abundant than kaolinite in the upper solum of many Ultisols (Shaw et al., 2010). Appreciable amounts of mica, smectite, and other 2:1 minerals have also been reported to occur in Ultisols (Nash, 1979; Harris et al., 1984; Karathanasis et al., 1986; Nash et al., 1988). The 2:1 minerals in these Ultisols were inherited from the parent materials instead of forming in situ from primary minerals or other phyllosilicates.

A common but minor mineral component of many Ultisols is gibbsite (Carlisle and Zelazny, 1973; Hajek and Zelazny, 1985). Because this mineral is an end product of silicate mineral weathering (Jackson et al., 1948), minor amounts should be expected to be found in Ultisols. Clay fractions of Ultisols developed from acid gneiss and schist in the southeastern United States, however, have been reported to contain as much as 70% gibbsite formed as a product of K feldspar weathering at the rock–saprolite interface (Losche et al., 1970; McCracken et al., 1971; Norfleet and Smith, 1989). Minor amounts of halloysite and Ti and Mn oxides are commonly present in Ultisols (Figure 33.79).

Iron oxides and oxyhydroxides are also common, but minor components in the clay fraction of Ultisols. Goethite is the most common Fe oxide mineral in most Ultisols, but many well-drained Ultisols have appreciable amounts of hematite. Analyses of 13 horizons from kandic and/or argillic horizons of Ultisols sampled within the Alabama (southeastern United States) Piedmont and Coastal Plain indicated that hematite composed 0%–11.4% of the clay (<2 μm) fraction, while goethite composed 0%–13.7% (Shaw, 2001). Hematite formation is favored by warm temperatures and distinct dry seasons (Schwertmann and Taylor, 1989), which are environmental conditions commonly associated with Ultisols.

33.12.6.2 Sand and Silt Minerals

The sand and silt fraction of Ultisols commonly is dominated by quartz, and many Ultisols have >90% quartz and other resistant minerals in their sand and silt separates. However, weakly to moderately developed Ultisols may have appreciable quantities of mica, feldspars, and other weatherable minerals in their

coarse fraction (Robertus et al., 1986; Norfleet and Smith, 1989; Bockheim et al., 1996).

33.12.7 Physical Properties

33.12.7.1 Bulk Density, Coefficient of Linear Extensibility, Water Retention, and Hydraulic Conductivity (*K*)

Bulk density, COLE, water retention, and hydraulic conductivity of Ultisols vary considerably depending on soil and horizon properties including particle size distribution, SOC content, mineralogy, macroporosity, presence of fragipans, parent material, presence of ironstone and plinthite, and, for surface horizons, management.

A horizons of uncultivated Ultisols often have lower bulk density than subsoil horizons, but with tillage and the accompanying loss of organic matter, compaction, and aggregate breakdown, the A horizon may become as dense or more dense than underlying Bt horizons (Table 33.55; Hubbard et al., 1985). Shrink/swell potential for kaolinitic Ultisols commonly is low reflecting the abundance of kaolinite and other low activity minerals (Table 33.53; Hubbard et al., 1985; Southard and Buol, 1988a), but COLE values up to 0.157 have been reported for Bt horizons from Ultisols with smectitic mineralogy (Karathanasis and Hajek, 1985; Griffin and Buol, 1988). However, smectitic Ultisols with high shrink/swell potential often lack wide cracks common to Vertisols and Vertic subgroups of other orders (Karathanasis and Hajek, 1985).

[a] Area of pores >0.05 mm equivalent circular diameter determined from impregnated polished blocks with image analysis.

[b] The BC horizon had insufficient dyed area for evaluation of pore area.

Ultisols in fine-loamy or fine particle size families would generally be considered capable of retaining and supplying sufficient moisture for plant growth in humid climates (Table 33.55). However, water often becomes a limiting factor for crop growth and yield for Ultisols in sandy or coarse-loamy particle size families, lithic subgroups, or that have thick sandy epipedons (Arenic and Grossarenic subgroups).

Most studies of hydraulic properties of Ultisols have found macroporosity to be the best predictor of saturated hydraulic conductivity (Ks) (O'Brien and Buol, 1984; Southard and Buol, 1988b). Preferential flow paths in Ultisols in the Piedmont and Coastal Plain of Georgia have textures similar to the matrix of the horizon, but the preferential flow zones have a significantly greater number and area of pores >0.05 mm diameter (Table 33.56; Shaw et al., 1998; Franklin et al., 2007). Formation of coarse pores in Ultisols is most often attributed to microfabric alteration and channel formation by roots and burrowing organisms (O'Brien and Buol, 1984; Southard and Buol, 1988b; Shaw et al., 1998; Franklin et al., 2007).

33.12.7.2 Infiltration and Surface Crusting

In many Ultisols, one factor affecting infiltration of water is formation of a surface crust or seal. For 25 Ultisols from the southeastern United States tested under 50–90 mm h^{-1} simulated rainfall, infiltration rate decreased rapidly during the first 10–20 mm of the rainfall event, and the infiltration rate at the end of rainfall was less than 10 mm h^{-1} for all of the soils (Miller and Radcliffe, 1992). In general, Ultisols in this region with sandy loam texture and high amounts of water dispersible clay are most prone to crusting. Soils higher in clay tend to take longer to form a surface crust, and sands and loamy sands form only weakly expressed crusts (Miller and Bahruddin, 1986; Radcliffe et al., 1991; Miller and Radcliffe, 1992; Chiang et al., 1993).

Because energy inputs from rainfall are needed to form surface crusts, crusting is minimal if the soils have residue or vegetative cover and organic matter is maintained in the upper part of the soil. For Ultisols in the Piedmont of Georgia, infiltration rates after 1 h of simulated rainfall were about 40% higher for soils that had been under no-tillage for 5 years than for soils that had been conventionally tilled (Table 33.57; Bruce et al., 1992).

33.12.8 Chemical Properties

The requirement that Ultisols have base saturation <35% in the lower part of the subsoil carries with it certain associated properties including low pH, potentially high Al saturation, appreciable weathering and associated kaolinitic mineralogy, and in many cases, relatively high contents of Fe and Al oxides and oxyhydroxides. This suite of properties has significant impact on the chemical properties of Ultisols and how these properties affect use and management of this soil order.

33.12.8.1 Cation and Anion Exchange Capacity

The CEC of Ultisol horizons depends on the amount and type of clay, Fe, Al, and Mn oxide content, organic matter content,

TABLE 33.57 Comparison of Organic C, Aggregate Stability, Infiltration Rate, and Percentage Moist Days under Conventional and No-Till Cropping Systems

Cropping System[a]	Organic C (g kg^{-1})	Aggregate Stability (g kg^{-1})	Infiltration Rate[a]		Moist Days,[b] % of Growing Season
			Residue (mm h^{-1})	Residue Removed (mm h^{-1})

[b] Moist days are defined as the days with soil moisture tension >0.1 MPa.

soil solution electrolyte concentration, and pH of the horizon. Reported CEC values for Ultisol horizons range from <3 to >20 cmol$_c$ kg^{-1} (Sanchez, 1976; Carlisle et al., 1985; Karathanasis et al., 1986). Generally, Ultisols with kaolinitic mineralogy have mostly pH-dependent charge and low CEC, while those with mixed or smectitic mineralogy have a greater proportion of fixed charge and higher CEC values.

Even when the net charge is negative, many Ultisols have an appreciable positive charge and anion exchange capacity (AEC). Gillman and Sumner (1987), in a study of four Ultisols from the Piedmont of Georgia, reported AEC values at the pH of the soil that ranged from 0.1 to 1.2 cmol$_c$ kg^{-1}, which was attributed to Fe and Al oxides in these soils. For Ultisols from Georgia and South Africa, Grove et al. (1982) reported AEC values ranging from 0.03 to 1.91 cmol$_c$ kg^{-1}. Measurable AEC has also been reported for Ultisols from tropical Australia and Peru (Gillman and Sumpter, 1986; Gillman and Sinclair, 1987).

33.12.8.2 Acidity and Exchangeable Aluminum

Below a pH of about 5.5, Al released from weathering of primary and secondary minerals is present as part of the exchange complex. An Al saturation of greater than 60% (measured as a percentage of the unbuffered CEC or ECEC) has been reported as the threshold that results in soil solution Al concentrations >1 mg L^{-1}, which may reduce yield in Al-sensitive crops (Nye et al., 1961; Kamprath, 1970; Sanchez, 1976). Farina and Channon (1991), however, observed yield reductions in maize for Al saturations >25% of the ECEC. Yields are also reduced at low pH due to Mn toxicity, and Ca, Mg, and Mo deficiency (Adams, 1984).

33.12.8.3 Phosphorus

Phosphate is specifically adsorbed by Fe, Al, and Mn oxides and amorphous or poorly crystalline aluminosilicates. Because of eluviation and weathering, surface horizons of most Ultisols have low contents of these components. Thus, P sorption is generally lower in Ultisols than in Oxisols and Andisols (Sanchez, 1976; van Wambeke, 1991). However, differences in crystallinity of Fe oxides among soils may confound this relationship within and among orders (Pratt et al., 1969; Fox et al., 1971).

33.12.9 Biological Properties

33.12.9.1 Organic Matter

Ultisols are commonly a fragile soil resource with low inherent soil quality (Norfleet et al., 2003). However, because these soils often exist in regions with long productive growing seasons and have favorable soil physical properties, Ultisols are often utilized for food, fiber, and timber production. Conservation management of these soils is critical for maximizing and sustaining productivity of agronomic systems. Numerous studies have documented the relationships between management, soil quality, productivity, and SOC in these soils (Reeves, 1997). A common misconception is that Ultisols have low contents of SOC compared with other soil orders. While Ultisols generally have lower amounts of SOC than Mollisols, Oxisols, and Andisols,

SOC levels in Ultisols are similar to those in Alfisols both within and across geographic areas (Sanchez, 1976). There is little difference in SOC content between Ultisols in temperate and tropical climates (Buol, 1973; Sanchez, 1976).

Cultivation of Ultisols has decreased SOC levels compared with relatively undisturbed ecosystems, and SOC contents decrease when these soils are converted from forest or pasture to row crop lands. Studies of Georgia (southeastern United States) Ultisols have found that organic matter content in surface horizons decreased from 20.5 to 16.6 g kg^{-1} 2 years after conversion from forest to intensive cultivation (Giddens, 1957), while soils in relatively undisturbed longleaf pine (*Pinus palustris* Miller) ecosystems in the Coastal Plain had 64% more SOC (relative) (0–30 cm) than conventional row crop lands (Levi et al., 2010). The use of conservation tillage, cover crops, and residue management (conservation systems) in row crop production can increase Ultisol SOC levels compared with conventional systems (Reeves, 1997). Bruce et al. (1992) reported that conservation systems increased SOC in the upper 15 mm of degraded Ultisols from 10.4 to 23.3 g kg^{-1} over a 5 year period. An investigation of 87 sites consisting mostly of Ultisols in the southeastern United States found SOC (0–20 cm) to be highest in pastures (38.9 Mg ha^{-1}), followed by conservation row crop systems (27.9 Mg ha^{-1}), and lastly, conventional row crop systems (22.2 Mg ha^{-1}) (Causarano et al., 2008). In addition, conservation system use in southeastern U.S. cotton (*Gossypium hirsutum* L.) production has been found to increase SOC quantities by 0.48 ± 0.56 Mg C ha^{-1} year^{-1} compared with conventional systems (Schwab et al., 2002; Causarano et al., 2006). Thus, Ultisols can play a significant role in managing SOC sequestration.

Increasing SOC in Ultisols significantly increases water stable aggregates and decreases runoff and interrill soil loss (Table 33.58; West et al., 1991, 1992; Bruce et al., 1992). Similarly, decreased runoff (Truman et al., 2005) and water dispersible clay (Shaw et al., 2003) were found for Alabama (southeastern United States) Coastal Plain Ultisols under conservation management with higher SOC quantities.

33.12.9.2 Biologic Populations and Processes

Populations of microorganisms in Ultisols are not appreciably different from soils in other orders. Surface horizons of most

TABLE 33.58 Interrill Soil Loss and Runoff from Three Ultisols with Varying Tillage and Surface Cover under 50 mm h^{-1} Rainfall Intensity for 1 h on 5%–9% Slopes

Tillage	Surface Condition	Interrill Soil Loss (g m^{-2})			Total Runoff (mm)		
		Soil 1	Soil 2	Soil 3	Soil 1	Soil 2	Soil 3
Conventional	Crusted	0.46	0.56	0.33	16	23	17
	Tilled	0.72	0.79	0.48	18	23	16
No-till	Bare	0.14	0.19	0.07	3	3	6
	Residue	0.07	0.03	0.02	1	1	1

Ultisols have acid pH values. Thus, fungi may comprise a greater proportion of the microbial biomass in these soils because of the greater ability of fungi to survive under acid conditions than other microorganisms (Alexander, 1977). Low pH has been reported to reduce rates of nitrification and denitrification in pure cultures (Alexander, 1977). Natural adaptation by microorganisms to local field conditions, however, probably alters the effects of pH and other environmental conditions observed in the laboratory.

33.12.10 Conclusions

Worldwide, Ultisols are a widespread soil resource, which because of their extensive weathering, low base saturation, and associated properties, are often considered to be unproductive. It is true that Ultisols, in general, have lower native fertility than Mollisols and Alfisols, and in areas where these orders are abundant, Ultisols are the less desirable soils. In many regions of the world, however, Ultisols are dominant or are the most productive soils available. Only with a thorough understanding of the genesis, properties, and response to management of these soils can the productivity of this valuable resource be maintained and enhanced.

33.13.1 Introduction

The deep, red and highly weathered soils of the tropics have long fascinated pedologists, particularly those from the temperate region. The uniqueness of these soils lies not only in their properties, but also in their geographic distribution being confined almost exclusively to the tropics. As this account is intentionally

concise, ample references are provided for those seeking additional or more detailed information.

33.13.2 Historical Background

In the early literature, the highly weathered soils of the tropics were identified as red soils, red loams, or red earths. In an historical report on travels in South India, Buchanan (1807) described soil material used for construction and called it laterite (Buchanan, 1807). The term was adopted by the pedologic community and is still used today with a wide variety of meanings (Alexander and Cady, 1962; Maignen, 1966). In 1949, a group of scientists proposed the term Latosols (Cline, 1975) that soon became popular and, by the midfifties, the concept of Latosols as highly weathered soils with a low negative charge was firmly established. Several soil classification systems developed during the 1950s and 1960s recognized such soils in a separate class with the nomenclature shown in Table 33.59.

The term Oxisol originated around 1954 (Smith, 1963, 1965) during the development of *Soil Taxonomy* (Soil Survey Staff, 1975). In 1978, an International Committee on the Classification of Oxisols (ICOMOX) was formed (Buol and Eswaran, 1988) to initiate discussions that would lead to an improved classification. Through circular letters and four international soil classification workshops held in Brazil (1976), Malaysia and Thailand (1978), Rwanda (1981), and Brazil (1986), the current state of knowledge of these soils was assembled and documented (Beinroth and Panichapong, 1978; Beinroth and Paramanathan, 1978; Camargo and Beinroth, 1978; Beinroth et al., 1983, 1986).

33.13.3 Concept and Classification of Oxisols

33.13.3.1 Perceptions

The rationale of the taxon of Oxisols is based largely on the concept of Latosols, which was developed to designate all zonal soils having their dominant characteristics associated with low silica:sesquioxide ratios, low base cation exchange capacity, low activity clays, and low content of weatherable minerals (Kellogg, 1949; Cline, 1975). These characteristics were selected because they were thought to manifest the effects of advanced pedogenesis under tropical conditions.

TABLE 33.59 Synonyms for Oxisols in Other Classification Systems

Synonym	Classification System	Sources
Sols ferrallitiques	French	Aubert (1958)
Latosols	Brazilian	Bennema et al. (1959)
Solos ferraliticos	Portuguese	Botelho da Costa (1954, 1959)
Oxisols	Ghana	Charter (1958)
Ferralsols		FAO–UNESCO (1971–1976)
Rotlehm	German	Harrassowitz (1930)
Laterites		Maignen (1966)
Red earths	British	Robinson (1951)
Kaolisols	Belgian	Tavernier and Sys (1965)

33.13.3.2 Definition

Simplified from the *Keys to Soil Taxonomy* (Soil Survey Staff, 2010), Oxisols may be defined as those soils that fail to meet the criteria definitive for Gelisols, Histosols, Spodosols, and Andisols but have either (1) an oxic horizon within 150 cm of the mineral soil surface and no kandic horizon within this depth, or (2) 40% or more clay in the surface horizon and a kandic horizon within 100 cm of the mineral soil surface that meets the weatherable mineral properties of the oxic horizon.

The definition of Oxisols has undergone significant changes since it was first published in *Soil Taxonomy* (Soil Survey Staff, 1975). Consequently, more soils now qualify for Oxisols; this should be kept in mind when consulting the earlier literature. It should also be mentioned that not all intensively weathered soils are Oxisols. Highly weathered soils with a marked clay increase below a coarse-textured surface horizon are by definition excluded from the Oxisols and are classified as kandic great groups of Ultisols and Alfisols (van Wambeke, 1992; Soil Survey Staff, 1998).

33.13.3.3 Diagnostic Criteria

Key to the identification of Oxisols is the presence of either an oxic horizon or a kandic horizon underlying a surface horizon with 40% or more clay. The key properties of the oxic horizon are its charge characteristics and negligible amounts of weatherable minerals. The charge characteristics are defined by the magnitude of the charge (CEC by NH_4OAc at pH 7.0 of <16 cmol$_c$ kg^{-1} clay) and the charge estimated by the Effective Cation Exchange Capacity (ECEC < 12 cmol$_c$ kg^{-1} clay). The low weatherable mineral requirement of <5% ensures that there are few weatherable minerals that could release plant nutrients. The particle size class of the oxic horizon is sandy loam or finer and its upper boundary is diffuse. To be diagnostic, the oxic horizon must have a minimum thickness of 30 cm and occur within 150 cm of the mineral soil surface.

The kandic horizon (Moormann, 1985) shares some of the properties of the oxic and argillic horizons. Like the argillic horizon, clay increases with depth but the charge characteristics are those of the oxic horizon. To be diagnostic for Oxisols, the kandic horizon must meet the weatherable mineral requirements of the oxic horizon, occur beneath a surface horizon that has 40% or more clay, and have its upper boundary within 100 cm of the soil surface.

Suborders of Oxisols are differentiated on the basis of soil moisture regimes, aquic conditions, the presence of a histic epipedon, and soil color. Defining criteria for great groups are the kandic and sombric horizons, plinthite, acric properties, and base saturation. The 14 differentiae used to establish subgroups are andic-like properties, Al + Fe percentage, aquic conditions, CEC, ΔpH ($pH_{KCl} - pH_{water}$), histic epipedon, kandic horizon, lithic contact, organic C content, petroferric contact, plinthite, soil color, soil depth, and the sombric horizon.

At the family level, criteria include particle size class, mineralogy class, and soil temperature regimes. Soil mineralogy is an important factor, and eight mineralogical classes are recognized (Table 33.60). When the soil has >18% Fe_2O_3 or gibbsite in the fine earth fraction (<2 mm), the mineralogical class is determined by

TABLE 33.60 Mineralogy Classes of Oxisols

Mineralogy Class	Fe$_2$O$_3$ (%)	Gibbsite (%)	Kaolinite (%)	Halloysite (%)
Ferritic	>40			
Gibbsitic	0–40	>40		
Sesquic	18–40	18–40		
Ferruginous	18–40	0–18		
Allitic	0–18	18–40		
Kaolinitic	0–18	0–18	>50

the amounts of each of these. If there is <18% Fe$_2$O$_3$ (12.6% Fe) or gibbsite, the composition of the clay fraction is considered.

33.13.3.4 Taxa

The class of Oxisols has 5 suborders, 22 great groups, 213 subgroups, an estimated 400 families, and perhaps as many as 1000 soil series. The great groups and possible subgroups of the Oxisols are presented in Table 33.61.

33.13.4 Geography of Oxisols

33.13.4.1 Global Extent and Geographic Distribution

The Oxisols of the world comprise about 9.8 million ha (Table 33.1), approximately equivalent to 7.5% of the global and 25% of the tropical land area. The distributions of Oxisol suborders in South America, Africa, and globally are illustrated in Figures 33.80 through 33.82. Over 95% of the Oxisols occur in the

FIGURE 33.81   Distribution of Oxisols in Africa.

tropics (Table 33.2) where udox occupy 13.2% and ustox 7.9% of the land area. South America has the largest extent of Oxisols and is home to 57% of the world's Oxisols, most of them occurring in Brazil. In Africa, Zaire probably has the largest areas of Oxisols. In Southeast Asia, Oxisols only occur in small isolated areas with the largest presumed to be in Borneo (Kalimantan). In Oceania, there are small areas of Oxisols in Australia and on the islands of the Pacific and Caribbean Basins.

33.13.4.2 Extent and Geographic Distribution in the United States

Oxisols have not been officially identified in the conterminous United States and only occur on the islands of Hawaii, Guam, Micronesia, and Puerto Rico where they account for about 4.3% and 6.7% of the land area, in Hawaii and Puerto Rico, respectively (Table 33.62). Small isolated areas of Oxisols have been observed in the coastal hills of northern California formed from peridotite, but have not been established as a soil series.

33.13.5 Formation and Landscape Relationships of Oxisols

33.13.5.1 Factors of Oxisol Formation

Soil is the cumulative result of the interaction of pedogenetic processes, which are controlled by the factors of soil formation. Although the factorial approach to understanding soil formation has serious conceptual and operational limitations (Smeck et al., 1983; Wilding, 1994), it remains a unifying philosophy in pedology. The formation of Oxisols is, therefore, discussed here in the context of this paradigm.

33.13.5.1.1 Climate

With respect to rainfall, the definition of Oxisols implies two conditions. First, in the case of Oxisols with kandic horizons, there must be some time during the year when evapotranspiration exceeds precipitation as this appears to be a prerequisite for the formation of the kandic horizon (van Wambeke, 1992). Second, precipitation must exceed the capacity of the soil to retain water during some time of the year, so that water percolates through the solum (Miller, 1983). This causes the leaching of soluble weathering products and favors the residual concentration of kaolinite and sesquioxides (van Wambeke et al., 1983). The wide variety of tropical climates that meet these conditions corresponds to the udic, perudic, and ustic soil moisture regimes of *Soil Taxonomy* (Soil Survey Staff, 1998). The few Torrox that now have an aridic soil moisture regime are considered relics of a more humid climate in the past.

Regarding temperature, most Oxisol areas have mean annual air temperatures >15°C with minimal annual fluctuations and, therefore, have isothermic or isohyperthermic soil temperature regimes. A few areas in southern Brazil and South Africa may have a thermic temperature regime. The climate conducive to the formation of Oxisols is thus typically humid tropical.

As most Oxisols have evolved over geologic time periods, consideration of the paleoclimate is essential for understanding and analyzing their development.

33.13.5.1.2 Parent Material

A distinction must be made between transported or allochthonous and residual or autochthonous parent materials. Autochthonous parent materials have weathered in situ, whereas allochthonous materials have been transported by fluviocolluvial processes. The sediments that form the parent material of Oxisols have frequently been preweathered and may have gone through more than one weathering and transport cycle. Where Oxisol development occurs in situ, the parent material is usually saprolite, which is a highly weathered parent rock that, unless it is collapsed, still preserves most of the original rock fabrics. In terms of area, the allochthonous Oxisols are more extensive than the autochthonous (Tavernier and Eswaran, 1972). The allochthonous Oxisols on the Brazilian and Guayanian Shields (Lepsch and Buol, 1974; Lepsch et al., 1977) and the Central African Plateau (Ruhe, 1956) are formed in sediments on mid to upper Tertiary surfaces and are generally as deep as the sediments. In Hawaii, geomorphological evidence, underlying rock weathering degree, and island age and time frame of cessation of volcanic ash production suggest that these soils have formed from basaltic volcanic ash.

33.13.5.1.3 Biota

There appear to be no clear cause and effect relationships between vegetation and the geography of Oxisols as they occur under both rainforest and savannas (van Wambeke et al., 1983). Termites and ants, however, may play an important role in the formation of Oxisols. Lee and Wood (1971) studied the termite activity in soils and its effect on modifications in the solum. van Wambeke (1992) cites a French study which reports that the amount of soil that termites displace varies between 300 and 1000 kg ha^{-1} year^{-1}, and that their mounds typically comprise 250 m^3. Leaf cutter ants not only transport soil particles upward but also carry large amounts of plant tissue below the surface. A comprehensive account of the role of termites and the mesofauna in tropical pedogenesis has been compiled by van Wambeke (1992).

33.13.5.1.4 Relief

Oxisols occur on many landforms, including uplands, backslopes, pediments, interfluves, and river and marine terraces. The one characteristic that the loci of autochthonous Oxisols have in common is geomorphic stability over usually long periods of time. Commonly, this implies low slope gradients. Small gradients, however, are not necessarily an indication of stability or geomorphic age as a level surface may be a recent floodplain or a Tertiary peneplain.

33.13.5.1.5 Time

The time required for the formation of Oxisols obviously depends on the other pedogenetic factors, notably the weatherability of

the parent rock, the composition and weatherability of transported parent materials, and the climate and its fluctuations over time. There is much scope for variability in these conditions, and consequently, in the age of Oxisols.

For Oxisols developed in transported sediments, their geologic age determines the actual maximum time available for soil formation. In Puerto Rico, for example, Oxisols have developed in preweathered materials on marine terraces of Quaternary age, but the autochthonous Oxisols of the interior commonly occur on Pliocene or Miocene surfaces that have been exposed to subaerial weathering for as long as 15 million years (Beinroth, 1981). Oxisol landscapes of comparable age have been reported in Africa, South America, and Australia (Miller, 1983). Oxisols in Hawaii can be less than 1 million years old.

33.13.5.2 Processes of Oxisol Formation

Various processes combine to produce, either concurrently or sequentially, the unique features of Oxisols. Prominent among these processes are those that (1) lead to the intensive weathering of primary minerals and the removal of soluble weathering products, the formation of 1:1 lattice clays, and the residual accumulation of sesquioxides, and (2) cause an increase of silicate clay in subsurface horizons. The first process, collectively known as laterization, is of paramount importance in the formation of most Oxisols. It involves desilication, ferrallization, ferritization, and allitization and causes the chemical migration of silica out of the solum and the relative concentration of sesquioxides in the soil. Formation of Fe coatings or aggregation at the expense of quartz grains is a common process in the tropical environment (Padmanabhon and Mermut, 1996).

Clay increase with depth that is diagnostic for the kandic horizon may result from (1) the process known as lessivage that causes clay illuviation and results in a clay maximum or bulge in the subsoil; (2) vertical downward translocation of clay without accumulation in an illuvial horizon. French pedologists refer to this process that leads to lighter textured surface horizons as appauvrissement or impoverishment (van Wambeke, 1992); (3) clay depletion in the soil surface may be caused by the selective removal of fine particles from the surface soil by erosion or mesofauna; (4) in Oxisols that are seasonally flooded, ferrolysis can cause the destruction of clay in the topsoil (Brinkman, 1970); (5) as postulated by Simonson (1949), in situ formation of clay in the B horizon may occur; and (6) lithological discontinuities may account for textural changes in the solum. In the past, the process of podzolization has been associated with Oxisols, but the evidence for it is intangible.

The formation of plinthite is often considered an extreme manifestation of laterization. The Soil Survey Staff (2010) characterizes plinthite as an Fe-rich, humus-poor mixture of sesquioxides, clay, quartz, and other diluents that commonly appear as dark red mottles in platy, polygonal, or reticulate patterns and generally forms in a horizon that is saturated with water for some time during the year. In a moist soil, plinthite is soft enough to

be cut with a spade, but it changes irreversibly to ironstone or petroplinthite when exposed to repeated wetting and drying. Plinthite (Eswaran and Raghumohan, 1973) is a diagnostic feature of many soils which are hydromorphic or have gone through a hydromorphic phase during their evolution. Hardening of plinthite takes place slowly when the ground water table is lowered and the soil surface ground cover is removed. If the surface soil horizons are eroded, the underlying plinthite is exposed and hardens rapidly to form petroplinthite (Sys, 1968; Eswaran and Raghumohan, 1973). A related feature is the development of a petroferric contact, which is an abrupt boundary between soil material and an underlying layer of cemented petroplinthite gravel that is hard and impermeable to both roots and water. The definition, genesis, and kinds of plinthite and petroplinthite have been discussed in detail by van Wambeke (1992). The upland soils of Palau and Yap, where eroded and degraded, exhibit surface layers dominated by irregular jagged and vesicular ironstone gravel and gibsite pendants. The uneroded, nondegraded adjacent soils however do not exhibit plinthite (Smith, 1983).

Gleization, which is a process of importance in the formation of some Oxisols, refers to the reduction of Fe and Mn under seasonally anaerobic soil conditions and produces bluish to greenish gray matrix colors with or without yellowish brown, brown, or black mottles and ferric and manganiferous concretions. These redoximorphic features are striking characteristics of the aquic subgroups.

The transformation of raw organic material into soil organic matter (SOM) known as humification occurs in all Oxisols, but is of particular importance in the humic and histic subgroups. A related process is the illuviation of humus that results in the formation of the sombric horizon which is a dark colored subsurface horizon found in soils on old geomorphic surfaces of Central Africa and parts of South America (Eswaran and Tavernier, 1980). Although its origin and genesis are still being debated, it is used as a diagnostic horizon in *Soil Taxonomy* because it is a distinctive feature in an otherwise nondescript soil (Eswaran et al., 1986). Oxisols with sombric horizons are restricted to the cool high plateaus of the tropics at altitudes between 1400 and 3000 m above sea level that have isothermic or colder temperature regimes and a udic soil moisture regime (van Wambeke, 1992).

In summary, a broad range of environmental determinants, and pedogenetic processes and mechanisms may be involved in the formation of Oxisols. Yet, there is no single set of formative factors, processes, and mechanisms that could account for the formation of all Oxisols. The fact that the causative conditions may not have been the same or may have operated at different intensities over time, and may have occurred simultaneously or sequentially, adds complexity to Oxisol genesis.

33.13.5.3 Landscape Relationships

The geomorphic evolution of the landscape is an important factor that is more important in the formation of Oxisols than in many other kinds of soil. As pointed out by Daniels et al. (1971), the occurrence of Oxisols, as that of other soils, is controlled by the interaction of geomorphic and other formative factors and the resulting rates and degrees of expression of pedogenic processes. Beinroth et al. (1974), Lepsch and Buol (1974), and Lepsch et al. (1977) provide illustrative examples of landscape relationships of Oxisols in Hawaii and Brazil that invariably show that Oxisols occupy geomorphic positions that are older and more stable than the surfaces where Ultisols and Inceptisols occur with which they are geographically associated. However, the recent introduction of the kandic horizon, which may be diagnostic for both Ultisols and Oxisols, has blurred the geomorphic boundary between the two orders. In the case of some Hawaiian Ultisols, a truncated oxidic paleosol is overlain by oxidic depositional material of ash origin. Although no significant clay percent differences are present between the two materials, the presence of clay films on the paleosol results in the Ultisol classification but physical and chemical properties and behavior are those of an Oxisol.

33.13.6 Properties

33.13.6.1 Macromorphology

Compared with the often strikingly horizonated soils of other orders, the field morphology of most Oxisols is visually rather uniform. They nevertheless have some distinguishing attributes. Color is a prominent feature of Oxisols. The surface horizon of most lowland Oxisols is a thin, reddish to yellowish colored ochric epipedon. Oxisols at high elevations (>1000 m) frequently have a dark-colored, humus-rich surface horizon (Ruhe, 1956), which may qualify for a mollic or umbric epipedon. Many Oxisols of Central Africa also have a dark-colored layer, the sombric horizon, in the subsoil. As Table 33.63 indicates, subsurface colors range from light gray in the Aquox to various hues of red in the upland Oxisols and are generally a function of the Fe content of the original material or rock (Eswaran and Sys, 1970). Color is also related to the kind of Fe minerals, with goethite producing yellow colors and hematite red colors. Presence of colloidal organic matter darkens the soil. Although organic carbon may be 4% or more, iron oxides dominate the color leading to the typical designation of an ochric epipedon. If there is a fluctuating groundwater table, mottles or plinthite may form in the oscillation zone. If the soil remains saturated with water for long periods, reduction and removal of the Fe results in a whitish horizon.

The texture of Oxisols may vary from sandy loam to clay. A characteristic feature is that the macro structural elements are weak in the subsoil. When the soil is gently pressed between the thumb and forefinger, the material collapses or fails abruptly. This is probably a good field indicator for an oxic horizon. In surface layers with higher clay contents, macrostructure can be moderate to strong, fine to medium subangular blocky. Excessive tillage however can reduce this condition to a seemingly single grain appearance of silt and sand sized microaggregates.

Many Oxisols have stone lines with the stones being quartz or petroplinthite gravel (Ruhe, 1956). The stone line is a mark of a lithologic discontinuity indicating that the material above

the line was deposited or formed at a different period than the material below. Stone lines frequently suggest that the soils are formed on transported deposits and point to the allochthonous nature of the material (van Wambeke, 1992). Some Oxisols have multiple stone lines.

33.13.6.2 Mineralogy and Micromorphology

The unique physical and chemical properties of Oxisols result mainly from the mineralogical composition of the colloidal fraction (Uehara and Keng, 1975; Herbillon, 1980). To have a CEC < 16 cmol$_c$ kg⁻¹ clay by NH$_4$OAc at pH 7.0, the clay fraction must be dominated by low activity clays such as kaolinite. Iron oxyhydroxide minerals, such as goethite, hematite, and ferrihydrite, are usually associated with kaolinite, but in some Oxisols, the Fe minerals predominate (Jones et al., 1982), particularly in soils belonging to ferruginous or ferritic families. The Fe minerals

can have a high positive charge (Jones and Uehara, 1973), which accounts for the special physical and chemical properties discussed later.

Gibbsite is present as a secondary mineral in many Oxisols (Eswaran et al., 1977). Weathering of primary minerals releases Si and Al; Si is lost in the soil solution while the Al crystallizes as gibbsite, mostly as nodules. The gibbsite crystals in the nodules are well crystallized as shown in the SEM micrograph taken at a magnification of ×2500 (Figure 33.83). The crystals are euhedral and twinning is common. Typically, gibbsite crystals have the size of fine silt, although dense pendants of almost pure gibbsite with the morphology of the root channels they formed in can be observed in highly degraded Oxisols of Palau (the Babelthuap Series). Oxisols usually have more gibbsite in the silt than in the clay fraction. It is for this reason that gibbsitic families are defined on the basis of the amount of gibbsite in the fine earth (<2 mm) fraction.
FIGURE 33.83 Scanning electron micrograph of a gibbsite nodule in a Gibbsiudox from Malaysia; the gibbsite crystals are typically euhedral and fine and medium silt size; magnification × 10,000.

The other frequent mineral in Oxisols is goethite (Eswaran et al., 1978). Plinthite, laterite, or petroplinthite frequently exhibit characteristic forms of goethite aggregates in thin sections as illustrated by the SEM micrograph (×10,000) in Figure 33.84. The goethite crystals have a typical lenticular shape and

FIGURE 33.84 Scanning electron micrograph of a geothite in a laterite fragment. The crystals have a lenticular habit with split edges; laterite sample from Angadipuram, Kerala, India, which is the type locality of the Buchanan lateriate; magnification × 25,000.

appear welded together, which gives the petroplinthic material its strength. Goethite and hematite have different habits and show different crystal forms.

In most Oxisols, the fabric is homogenous without too many specific entities like those illustrated previously (Buol and Eswaran, 1978). In some oxic horizons, a thin lining of ferriargillans (yellow coatings on the void walls) may be present. Ultrathin sections under TEM suggest that the combination of random orientation of clay particles, organic matter, and aggregates of Fe-bearing minerals accounts for the isotropic nature of the aggregates under a petrographic microscope (Santos et al., 1989). The presence of the clay skins is evidence of the transitional nature of the soil, and that clay illuviation and accumulation was an important process. The transitional nature is indicated by the kandi prefix in the soil name.

Unless eroded, the surface horizons of Oxisols have a relatively high organic matter content with high biological activity including the presence of fungal hyphae and fruiting bodies, which are generally indicators of good soil quality. Typical for the drier tropics is the presence of large termite nests, which can reach 5 m in height. Some species of termites are subsoil dwellers and their galleries may extend several meters into the soil. Bioturbation of the soil is, therefore, an important soil-forming process in tropical soils.

Oxic horizons have a friable consistency. When a large soil clod is gradually crushed in the hands, the material disaggregates and small rounded bodies become evident. These features, which are only observed in Oxisols, have been referred to as pedovites or soil eggs by Belgian pedologists and "earthy lumps" in Hawaiian pedon descriptions. The excellent and stable structure of Oxisols, and their high macroporosity resulting in moderate to moderately rapid infiltration rates, make them resistant to erosion. Where intense tillage has reduced surface structure to microaggregates and has created tillage pans, erosion rates can be dramatically increased.

33.13.6.3 Chemistry and Physics

The chemistry and physics of Oxisols are inextricably linked to the surface charge characteristics of minerals in the clay fraction. Unlike in most other soils, the surface charge of minerals in Oxisols is pH dependant and varies in magnitude and sign. Oxisols, however, are not the only soils dominated by variable charge systems. Andisols, Ultisols, and Histosols can be even better examples of soils with variable surface charge, so that the attribute that makes Oxisols unique is the low permanent negative charge of the silicate clay minerals in the clay fraction. Important physical and chemical properties of selected pedons representing Oxisol suborders are summarized in Tables 33.63 and 33.64.

The sign of the charge is readily established by the sign of the difference in pH (ΔpH) in the following equation:

$$\Delta pH = pH_{KCL} - pH_{water}$$

Oxisols with a positive ΔpH are rare, but not difficult to find if one knows where to look for them. They are rare because

ΔpH, pH in KCl minus pH in H$_2$O; pH$_o$, pH of soil at the zero point of charge where positive and negative charges are equal; OC, organic carbon content.

positive ΔpH values almost always occur in the subsoil. They rarely or almost never occur in surface horizons because negatively charged SOM masks the positive charge in the mineral–organic mixture. Organic matter, like the mineral fraction in the oxic horizon, has variable charge characteristics. The difference lies in their respective points of zero charge (p.z.c.) being <pH 3 for organic matter and >7 for oxic materials. Since soil pH values rarely fall below 3, SOM is net negatively charged in most soils.

The p.z.c. for material in the oxic horizon is highly variable ranging from pH 3–6. As a rule, it increases as organic C decreases and the silica/sesquioxide ratio of the clay fraction decreases. Hematite (Fe$_2$O$_3$), for example, has a p.z.c. of 8.5 (Parks and de Bruyn, 1962). In this sense, Oxisols are products of desilication, and the end products of desilication are the oxides and hydrous oxides of Fe and Al.

Over 82 years ago, Mattson (1928, 1932) showed that p.z.c. increased as the silica/sesquioxide ratio decreased. He also showed that the pH of the gel shifted toward the p.z.c. on leaching with distilled water, which he called isoelectric weathering. This concept is useful in explaining the chemical and physical behavior of Oxisols and related soils dominated by low activity clays. This concept is best illustrated with an example, and one of the best examples is the Nipe soil of Puerto Rico and Cuba (Anionic Acrudox in Table 33.61). (Data is for the original Type location in Puerto Rico. This site has been urbanized. The new type location (data not presented) classifies as a Typic Acrudox. The isoelectric properties of the Nipe soil are mainly determined by the p.z.c., which is measured as pH$_o$ (pH at which positive and negative charges on variable charge surfaces are equal).

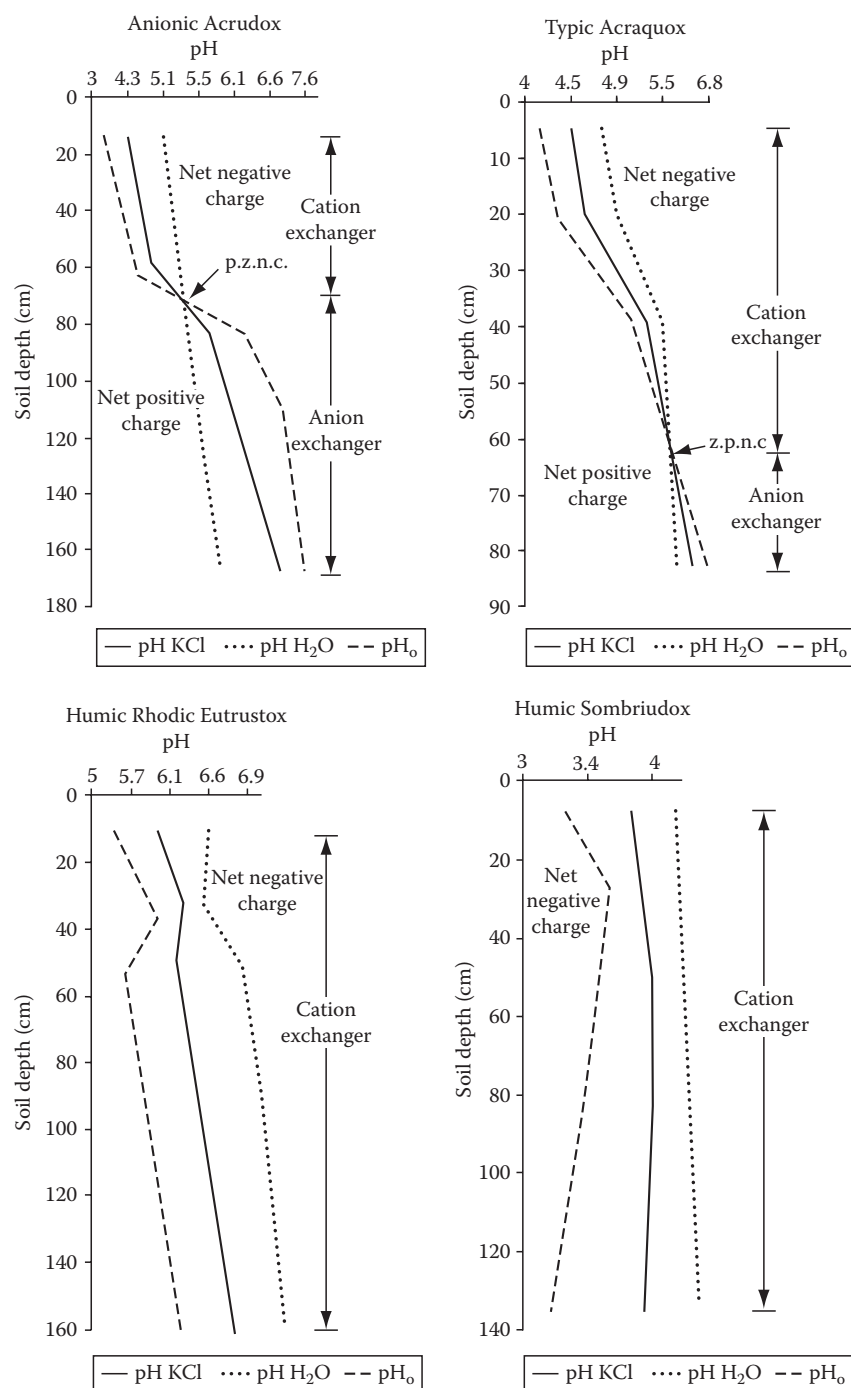
When ΔpH = 0, pH values measured in M KCl and water are identical indicating that when the material is net negatively


FIGURE 33.85 Surface charge characteristics of Oxisols of different suborders.

charged, pH_o is always lower than pH_{KCl} and vice versa. This does not apply to materials with significant amounts of permanent charge minerals.

The Nipe soil, like all Acric Oxisols, is a cation exchanger in the surface horizon and an anion exchanger in the subsoil. Charge characteristics of the Nipe soil and three other Oxisols are illustrated in Figure 33.85. The anion exchange capacity (AEC) of the subsoil can lead to unexpected consequences. In Hawaii, for example, 3–11 Mg NO_3–N ha^{-1} have been measured in the subsoil

and deep saprolite underlying Oxisols and Ultisols (Deenik, 1997), which explains the low NO_3^- levels in the groundwater underlying these soils even after nearly a century of intensive farming. Although the NO_3^- remains trapped above the water table, pesticides banned decades ago continue to enter the groundwater. Had the soil minerals been of the permanent charge type, the NO_3–N would have reached the groundwater many years ago.

In cation impoverished Oxisols such as the Nipe soil, lime is often added as a Ca fertilizer rather than an amendment.

But because lime raises pH and increases negative charge, Ca^{2+} ions remain in the limed layer and do not move to the impoverished subsoil. To circumvent this problem, gypsum and magnesium sulfate are favored over calcite or dolomite whenever the aim is to raise subsoil Ca and Mg. The factors determining movement of surface-applied amendments in variable charge soils are discussed in detail by Sumner (1995).

The acidic organic matter near the surface and the basic oxides in the subsoil determines, in essence, the chemical properties of the Nipe soil. In most Oxisols, the desilication process has not progressed as far as in the Nipe series. In such instances, the subsoil pH will be lower than that of the Nipe soil because the p.z.c. will be lowered by the higher Si content.

An opposing process that counteracts desilication is humification of the desilicated weathering products. Humic acids, like silicic acid, have a p.z.c. below 3. At pH levels normally encountered in soils, humus and silica are net negatively charged, so that they have strong affinities for positively charged sesquioxides. In one sense, organic matter adsorption on oxide surface has nearly the same effect as resilication of the oxides (Uehara, 1995). The surface of quartz is chemically similar to silicic acid, but its low specific surface renders it virtually inert. Desilicated Oxisols can be rejuvenated by additions of soluble silicates. Large crop responses to additions of calcium silicate above those obtained from similar lime applications have been reported (Plucknett, 1971).

The moisture characteristics curves of well-aggregated Oxisols show two major desorption zones. Water in the interaggregate pores drains rapidly between 0 and -0.01 MPa. Another desorption zone occurs when the intraaggregate pores begin to drain at about -15 MPa (Sharma and Uehara, 1968a, 1968b), which results in a bimodal pore size distribution (Tsuji et al., 1975; Bui et al., 1989). Some have referred to Oxisols as behaving like aggregated sands because of their stable aggregates and high macroporosity. This description tells only half the story. The aggregates that remain nearly water saturated beyond the wilting point impart additional properties to Oxisols. The water-saturated aggregates increase volumetric heat capacity and lower thermal diffusivity. Crops such as pineapple respond to practices that raise subsoil temperature. In Hawaii, plastic sheets used to increase the effectiveness of soil fumigants also aid the crop by raising subsoil temperature (Ekern, 1967). The intraaggregate water retained at high negative pressures also affects tillage operations. This intraaggregate water is freed under the shearing action of tillage implements and causes the soil to adhere to the implement. Some farmers solve this problem by bolting a teflon sheet onto the implement's shearing surface.

In summary, the physics and chemistry of Oxisols are strongly influenced by the extent to which desilication has occurred. Basic and ultrabasic parent materials readily desilicate and produce soils that approach the central concept of Oxisols. Desilication is also aided by warm and humid conditions, so that when Oxisols occur outside the tropics, they are almost always associated with ultrabasic rocks.

33.13.7 Conclusions

Oxisols occupy about 25% of the land area of the tropics where they are the single most extensive soil type. Yet, historically they have been perceived as agriculturally unproductive and problematic for management; under low input agriculture, yields are in fact low, risk is high, and the potential for land degradation is also high (Sanchez and Salinas, 1981). The negative notion of the poor agronomic performance derives substance from the inherent chemical constraints of Oxisols, which include, to varying degrees, a low nutrient retention capacity, anion adsorption, Ca deficiency, and Mn and Al toxicity (van Wambeke, 1974; Sanchez, 1976). It is also true that the inputs required to correct these constraints may be economically prohibitive for many farmers, and in places where better endowed soils are available, the Oxisols are, therefore, at a distinct comparative disadvantage (van Wambeke, 1992). Nevertheless, with science-based management that employs the tools and techniques of modern agriculture, Oxisols can be managed to be both economically and sustainably productive. Consequently, no less an authority than Charles E. Kellogg stated that "some day the most productive agriculture of the world will be mostly in the tropics, especially in the humid parts" (Kellogg, 1967). Presumably, this assessment is based on the realization that the favorable physical attributes of Oxisols outweigh their chemical limitations. While the latter can be amended with purchased inputs, good soil structure cannot be bought. That said, excessive tillage can destroy macro aggregation.

Oxisols are the dominant soils in the humid tropical forest ecosystem, a pristine environment that constitutes an enormous reservoir of sequestered carbon and unique ecological niches of great biological diversity, in addition to being a resource for food, timber, medicine, and other products for people. Yet, the resource-poor farmers invading these areas practice shifting cultivation, and slash and burn agriculture has become the most extensive form of agriculture in the tropics. As a result, over 15 million ha of forests are being burned annually, and some plants and animals are lost permanently when their habitats are destroyed. Moreover, the resilience of these ecosystems is so low that complete regeneration may not be achieved.

Oxisols constitute a major land resource and one of the few remaining frontiers for agricultural development, particularly in Africa and South America, and also support the largest areas of tropical forests. Their conversion to agricultural land will be at the expense of the forest with the concomitant loss of biodiversity and negative impact on global climate. It is imperative, therefore, to develop viable alternatives to traditional agricultural systems. If this challenge can be met successfully, the rewards are not only to provide a means for millions of people to extricate themselves from poverty, but also to ensure the survival of the tropical forests. Landuse policies guided by an understanding of the nature, properties, and ecological functions of Oxisols are critical to sustain the integrity and productivity of these land resources.

34.1 Introduction

Sustainable development has become a key goal of various international agencies, and the role of the land in achieving this is increasingly being recognized. More efficient land use is needed to, for example, feed 9 billion people in 2050, to combat climate change, and to enable sustainable biofuel production (e.g., Hartemink and McBratney, 2008). Studies have explored the potential world food supply and associated environmental quality issues, among them land degradation (Penning de Vries et al., 1995). At another scale, new farming systems are being developed to optimize fertilizer and biocide use, applying modern information technology, summarized as precision agriculture (PA; CIBA Foundation, 1997; Bouma et al., 1997a; Stoorvogel et al., 2004c). Regional planners consider alternative land use scenarios combining agricultural production with nature conservation and other functions such as water storage (Bouma et al., 2008). In all cases, land use is the core issue to be studied, while socioeconomic considerations often play a crucial role as well. Consideration of actual and potential land use as a function of land properties fits under the broad umbrella of land evaluation as advocated by FAO (1976, 1983). Land evaluation

can be realized with descriptive, qualitative methods but increasingly includes quantitative simulation models for crop production, land use, and environmental impacts in combination with geographic information systems. All these methods need to be fed with adequate soil data, often derived from soil surveys (e.g., Bouma, 1994). This sometimes occurs mechanistically using existing databases with little attention to natural soil dynamics or landscape relationships, and this may lead to unrepresentative results. Soil survey has much to offer, but this expertise has to be applied and presented more effectively than at present. Soil survey interpretations in soil survey reports present broad possibilities and limitations for a variety of land uses for each mapping unit. However, these represent rather narrowly defined land uses as compared with land evaluation that enables the actual assessment of land performance. Aside from the variation in space, there is also the need to consider variation in time, be it days, growing seasons, or decades. Increasingly, land evaluation is realized in close interaction with the stakeholders, ranging from farmers to planners and politicians. Innovative developments in land evaluation, emphasizing interdisciplinary approaches at different spatial and temporal scales, will be discussed in this chapter.

34.2 Land Evaluation: The FAO Framework

34.2.1 Definitions

Land evaluation is defined as follows:

> the process of assessment of land performance when used for specified purposes, involving the execution and interpretation of surveys and studies of land use, vegetation, landforms, soils, climate and other aspects of land in order to identify and make a comparison of promising kinds of land use in terms applicable to the objectives of the evaluation.

> **(FAO, 1976)**

Clearly, evaluating the performance of land has been the topic of many studies in the past in different disciplines. There is, for instance, a large amount of literature on land use planning from a regulatory and social perspective, but here the focus will be on agroecology as related to sustainable development. Adopting the international FAO approach has the advantage of using a widely known procedure in which definitions are so broad that they offer many opportunities for expansion and modification. Two elements stand out when considering the definition of land evaluation: (1) Performance can only be assessed when a specific land use has been defined. In other words, judgment cannot be made as to performance in general but only for specific types of land use. Land may, for instance, function quite well as a campground but poorly when growing a wheat crop. (2) Attention is paid not only to current land use but also to potential forms of land use, which may be more or less promising depending on the objectives of the evaluation.

Land is defined as follows:

> an area of the Earth's surface, the characteristics of which embrace all reasonably stable, or predictably cyclic attributes of the biosphere, vertically above and below this area including those of the atmosphere, the soil and underlying geology, the hydrology, the plant and animal populations and the results of past and present human activity to the extent that these attributes exert a significant influence on present and future uses of the land by man.

> **(FAO, 1976)**

A land unit is defined as follows:

> an area of land possessing specified land characteristics and/or land qualities which can be demarcated on a map. Land is often represented as a georeferenced land unit on soil maps, which present additional data on climate in a soil survey report.

> **(FAO, 1983)**

The broad term "land use" is specified in terms of land utilization types (LUTs), which define a particular type of land use in varying degrees of detail. In the context of rainfed agriculture, an LUT refers to a crop, crop combination, or cropping system with a specified technical and socioeconomic setting (FAO, 1983). When combining the Land Unit with the LUT, one obtains the so-called land use system (LUS) defined as a specified LUT practiced on a given land unit and associated with inputs, outputs, and possible land improvements (FAO, 1983). Previous work in Costa Rica has defined such LUSs also in terms of the type of technology (T) being used in each particular production system. They refer, therefore, not to a LUS but to a LUST, an example of which is provided in Table 34.1.

A key element in land evaluation is the assessment of land performance. This is done, in principle, by comparing the requirements of a particular type of land use with what the land has to offer. When the two match, the land is suitable for a particular LUST. When they do not match, suitability is less to varying degrees. Land suitability is correspondingly defined as follows: *the fitness of a given type of land for a specified kind of land use* (FAO, 1976). This matching process, which is central in land evaluation, is handled by defining land qualities and land characteristics. Land qualities are *complex attributes of land that act in a manner distinct from the actions of other land qualities in its influence on the suitability of land for a specified kind of use.* The matching process is realized by expressing both land use requirements and what the land has to offer in terms of land qualities and by comparing the two expressions.

Although this is not mentioned by FAO (1976), land qualities usually cannot be measured directly. Examples are the moisture supply capacity, the workability, and the trafficability of land. They vary over the years and are determined by land behavior over extended periods of growing seasons. Modern methods will be discussed later to determine land qualities.

TABLE 34.1   A Listing of Data Documenting an LUT with LUST for Maize, Sown January 15 on a Fertile, Well-Drained Soil, Typical for the Neguev Area of the Atlantic Zone of Costa Rica

Operation	Date	Labor (h)	Equipment	Materials
Land preparation	January 31, 1991	20	Machete	
Herbicide application	January 2, 1992	10	Knapsack sprayer	2 L Gramoxome
Sowing	January 15, 1992	10	Planting stick	20 kg local variety maize seed
Fertilizer application	January 30, 1992	10		50 kg ammonium nitrate
Harvest	May 15, 1992	50		100 bags dry cobs

Source: Adapted from Jansen, D.M. and R.A. Schipper (1995). A static descriptive approach to quantify land use systems. Netherlands Journal of Agricultural Science 43:31–46.

However, in the older land evaluation work, attempts were made to find proxies for land qualities based on land characteristics, which are *attributes of land that can be measured or estimated*. In this context, one may think of soil texture, organic matter, carbonate content, etc.

The basic elements of "classical" land evaluation have now been introduced. One has land that is being used for a particular purpose in a particular way. Not only current land use should be looked at but also other possible forms of land use that are of interest. One wants to assess land performance for these different alternative forms of land use and does so by comparing land requirements for each alternative form of land use with what the land has to offer. This matching process is made possible by defining important land qualities, often defined in terms of land characteristics in different classes. The overall analysis results in statements as to relative suitabilities of a given piece of land for a series of LUSs. Much practical experience with this system is reflected in the work of Sys et al. (1991) who provide excellent case studies. Some examples to further illustrate the procedure and to discuss some underlying concepts will be examined.

34.2.2 An Example

An example given by FAO (1983) addresses land suitability for sorghum (Table 34.2) and may serve to illustrate some basic decision steps to be taken that have general validity. Suitability of the land unit being considered is expressed in terms of highly, moderately, marginally, and not suitable. Three land qualities are distinguished: rooting conditions, oxygen, and nutrient availability. This selection reflects the expert judgment of the land evaluator. Quite possibly, other evaluators would have selected other land qualities. Because land qualities, as mentioned here, cannot be measured directly, land characteristics are used as proxies, called "diagnostic factors," and are as follows: drainage class (soil survey reports), effective soil depth (to be estimated from structure descriptions in soil survey reports), and soil reaction (pH). Clearly, some selections reflect lack of good data. Soil drainage classes are very broadly defined and only remotely related to O_2 diffusion. The effective soil depth is more direct but does not consider any particular demands by sorghum; it could apply to any crop. The pH, finally, is a very general indicator for nutrient availability, and its selection reflects an apparent desperate lack of information on the soil fertility status. Finally, the evaluator has to couple classes of the diagnostic factors somehow to demands by the sorghum crop (crop requirements) to arrive at the suitability classes. In summary, there are three moments when important decisions have to be made based on expert knowledge and data from the literature: (1) selection of land qualities, (2) selection of land characteristics to describe the land qualities, and (3) selection of gradations of these characteristics to form suitability classes based on estimated crop requirements.

34.3 Beyond Classical Land Evaluation

The classical land evaluation scheme has been widely applied and has influenced many land evaluation methodologies (e.g., Sonneveld et al., 2010b). Its application has been facilitated by automated computer-driven decision support systems (e.g., Rossiter, 1990), often with a strong agroecological focus. However, five problems have become clear over the years:

1. Even though the need to define clear land evaluation objectives in close interaction with stakeholders has been stressed from the start, the development of a mechanistic, rather sterile approach has been observed in which land suitability is defined for a large number of LUSTs (Sys et al., 1991). It is not clear who is asking the questions or, worse, whether the answers being provided address the questions that are really being raised. Thus, several projects have failed because of a lack of stakeholder participation (FAO, 2007).

2. Defining land qualities in terms of land characteristics has become a rather rigid qualitative procedure, even, and particularly, in automated computer-driven decision support systems, allowing little input from modern process-driven land research focused on landscape processes and climatic change.

3. The procedure is almost exclusively driven by the properties of the land, and even though the importance of socioeconomic conditions is acknowledged, little is done to take these conditions into account. Land use and its possible changes are usually more a reflection of socioeconomic developments in society than of differences in soil suitabilities for different forms of land use. Implicitly, classic land evaluation assumes that *use* follows *land*, while in reality more often *land* follows *use*. Think of roads and shopping centers on prime agricultural land. This requires a different approach than the soil-centered one.

TABLE 34.2 Land Qualities and Land Characteristics (Diagnostic Factors) for a Sorghum LUT, Expressed in Terms of Crop Requirements

Crop Requirement			Factor Rating			
			Highly Suitable	Moderately Suitable	Marginally Suitable	Not Suitable
Land Quality	Diagnostic Factor	Unit	s1	s2	s3	n
Oxygen availability	Soil drainage class	Class	Well drained/ excessive	Moderately well drained	Imperfectly drained	Poorly/very poorly drained
Rooting conditions	Effective soil depth	cm	>120	50–120	30–50	<30
Nutrient availability	Soil reaction	pH	5.5–7.5	4.8–5.5 and 7.5–8.0	4.5–5.5 and 8.0–8.5	<4.5 and >8.5

Source: FAO. 1983. Guidelines: Land evaluation for rainfed agriculture. FAO Soils Bulletin No. 52. FAO, Rome, Italy.

Moreover, land units, as distinguished in earth science, hardly ever correspond with legal units on which decisions are made. For example, a farmer farms a field with most often different land units, not a single one. A district or county where land use decisions may be made may cut through different land units, etc.

4. The procedure was implicitly defined as being scale independent. Most applications of classical land evaluation have been at the regional level, but many land use questions are raised at farm or field level or at the continental or world level. Not only are the questions then quite different (see (1) above) but procedures to be followed should be different as well.

5. Finally, there was a lack of dealing with uncertainties. Map units, agronomic relationships, and climatic variability are characterized by high levels of uncertainty, requiring expression of land use options and their effects in terms of probabilities. This aspect was not considered in the FAO framework.

What is now needed is a better evaluation of questions being asked at different spatial scales. Next, proper procedures need to be defined to deal with these questions, realizing a wide variety of stakeholders are involved. And, finally, the proper role of the land in affecting land use decisions needs to be defined. Certainly, decisions are not made for land units but for georeferenced surfaces on the Earth that may contain many land units.

34.4 What Is the Question?

Questions regarding land use vary a great deal. Let us analyze some of them:

1. A farmer wants to know how he can obtain a high and secure yield of profitable crops at minimal cost, while operating in line with increasingly detailed environmental laws and regulations. Cutting costs to be achieved by, for example, precision application of fertilizers and biocides or minimum tillage is increasingly important. He certainly is not interested to hear that his land is moderately suitable for wheat growing. He will already know that. He wants quantitative information in terms of what to do and when, where, and how to do it within the context of given environmental regulations.

2. An environmentalist will ask how agrochemicals use can be reduced or even abolished, thus avoiding leaching into ground or surface water. To answer such questions, detailed process-based simulation models may have to be applied at both farm and regional level to estimate the adsorption and leaching of agrochemicals as a function of management. Of course, the ideal is to combine the desires under (1) with those under (2), which is the basic concept of PA.

3. A regional planner may want to formulate alternative land use options within a region all in the context of achieving sustainable development. Here, the existing land evaluation procedure may be useful, but data are not specific enough

to allow quantitative trade-offs among environmental, economic, and social considerations for each of the options.

4. A policy maker may see options for land use in a region or a country, formulated by procedures under (3). His question, however, is how attractive options can indeed be realized? How can stakeholders be influenced to do the right thing: special educational efforts, taxes, bonuses, subsidies? Clearly, land evaluation does not primarily focus on such issues, but they are increasingly important for land use and should, therefore, be considered because in the end the success of any scientific activity will be measured by its effect on society. If land evaluation reports wind up on the shelf, the activity itself will turn out to be nonsustainable. This fourth question can be handled by considering the policy cycle to be discussed later.

Considering the range of questions that may be encountered, an exploratory approach is attractive, defining a number of realistic land use options for the area to be considered. The stakeholders or policy makers make a choice from options presented. The type of question to be answered is as follows: What are the options for land use? How can one optimize land use for certain objectives and what are the trade-offs between these objectives? When dealing with sustainable land use, a balance has to be found for each option between environmental, economic, and social objectives. Different groups of stakeholders or different political parties will have different affinities with different options. The primary task of land evaluation is not to develop and select the "best" option but to present a series of well reasoned and transparent and alternative land use options allowing a rational selection process. Whether or not selected options are realized in practice depends on the stakeholders, but scientists can still be involved in the selection and implementation process because—as stated above—they also have an interest that some of the options they have derived will materialize in practice. This can be achieved by following the policy cycle, including signaling, designing, deciding, implementing, and evaluation (e.g., Bouma et al., 2007). The exploratory approach does not predict but explores what have also been called "windows of opportunity," a challenging concept.

Bouma (1993) has discussed five case studies on land use at different scales, showing that each was associated with quite different questions, while knowledge used in answering the questions varied very much as well. We therefore first analyze the different types of knowledge involved in land evaluation.

34.5 Some Basic Elements in Land Evaluation

34.5.1 Considering Different Types of Knowledge: The Knowledge Chain

A diagram (Figure 34.1) has been helpful to illustrate the use of different types of knowledge when analyzing land use questions at different spatial scales (Hoosbeek and Bryant, 1992; Bouma and Hoosbeek, 1996). They considered two perpendicular axes,
FIGURE 34.1   Scale diagram showing a series of hierarchical scales (i levels) and modeling approaches expressed in terms of four characteristics, which are summarized in terms of knowledge levels K1–K5. (Reprinted from Bouma, J., and M.R. Hoosbeek. 1996. The contribution and importance of soil scientists in interdisciplinary studies dealing with land, p. 1–15. *In* R.J. Wagenet and J. Bouma (eds.) The role of soil science in interdisciplinary research. SSSA Special Publication No. 45. SSSA, Madison, WI. Soil Science Society of America.)

one ranging from qualitative to quantitative and the other from empirical to mechanistic. Different research approaches occur within the plane thus obtained: K1 represents user knowledge; K2 represents expert knowledge; K3 represents knowledge to be obtained through semiquantitative models, in which real soil processes are not known; K4 represents knowledge through quantitative models where processes are characterized in general terms; and K5 represents the same, but processes are described in great detail, which can imply that the entire soil/crop system cannot be characterized anymore, and attention is focused on one aspect only (Bouma et al., 1996a). The vertical axis represents the scale hierarchy, where the pedon level (the individual soil) occupies the central position (i level). Higher levels are indicated as i+, while lower levels are i−. The scale in Figure 34.1 ranges from molecular interaction (i − 4) to the world level (i + 6).

One can now place the classic land evaluation in the scheme at scale hierarchy of watershed or region while the knowledge level is K2. For other questions raised above, one needs different hierarchies and knowledge levels. For example, the farmer and environmentalist would require the i + 1 field scale and a K4 knowledge level to get the necessary quantitative answers for their questions. The regional planner would operate at level i + 4 and would need at least a K3 knowledge level, because the K2 level would be too descriptive not allowing a quantitative trade-off analysis. A planner would be smart, though, to combine K2 with K3, by restricting the more detailed analyses of K3 to areas where a simpler K2 analysis could not provide answers. For example, Van Lanen et al. (1992) made a land evaluation for Europe in which potential for crop growth was established. Using soil maps, they first screened out strongly sloping land and land with shallow bedrock using a K2 approach. Then, in the remaining 40% of the land area, they ran a K3 simulation model to predict crop growth. The K2 approach for these soils (land is

moderately suitable for wheat) would not have been satisfactory. This scheme introduces the possibility of combining approaches. Another example is derived from a study of De Vries et al. (1992). They did a study to determine the possible impact of acid rain on soil acidification. They dealt with nonagricultural areas without fertilization. They divided Europe (scale i + 5) (Figure 34.2) into grids, and for each grid, they determined the dominant soil type, using the soil map of Europe (K2 knowledge). Then, they selected a limited number of soil units (level i) that were considered to be representative for European soils (using K2 knowledge). In these soils, they made some detailed measurements of weathering rates (scale i − 4; knowledge level K5). Next, this knowledge was scaled back up, resulting in what is assumed to be effective K4 knowledge at the European level. It would have been impossible to make the detailed K5 measurements of weathering rates in all European soils. By using expert knowledge at different scales, measurements could be made more efficient. Ideally, measurements should always include a measure for reliability and accuracy. An overall K5 approach for all soils would have the highest reliability but would be too expensive. One must know how much is lost in terms of reliability when one goes from K5 to K4, K3, and K2. Decisions as to what to do can only be based on this type of information. The lines in Figure 34.2 represent a so-called research chain demonstrating how a given problem can be analyzed by combining knowledge at different scales. The study by De Vries et al. (1992) had a disciplinary character, covering one particular aspect of land use. The four questions raised in Section 34.4 have, however, a much broader scope focusing on sustainable land use and require therefore a more comprehensive and interdisciplinary approach than was needed in the study by De Vries et al. (1992), including consideration of the role of different disciplines and of the policy cycle. Before discussing the latter two items, it is important to discuss the role
FIGURE 34.2 Scale diagram for the study by De Vries et al. (1992) on acidification of European forests. Three hierarchical scales are distinguished. At each scale, different methods corresponding to different knowledge levels are applied, forming a knowledge chain. (Reprinted from Bouma, J., and M.R. Hoosbeek. 1996. The contribution and importance of soil scientists in interdisciplinary studies dealing with land, p. 1–15. *In* R.J. Wagenet and J. Bouma (eds.) The role of soil science in interdisciplinary research. SSSA Special Publication No. 45. SSSA, Madison, WI. Soil Science Society of America.)

of soil scientists within broad, interdisciplinary land evaluation approaches involving many colleague scientists and often also stakeholders and policy makers. This role is quite different from the one described by FAO (1976, 1983, 1993) where soil scientists were in charge.

34.5.2 Applying Soil Science in the Broader Context of Land Evaluation

Soil science is back on the global agenda as evidenced by policy documents of several international agencies, listing the importance of soils in studying the Millennium Development Goals, climate change, environmental degradation, hunger alleviation, and production of biofuels (Hartemink, 2008; Hartemink and McBratney, 2008). In this context, land evaluation, as discussed in this chapter, can and should play a crucial role. There are, however, some potential difficulties (e.g., Bouma, 2009). Broad issues, as listed, require an interdisciplinary and participatory approach involving many scientists, stakeholders, and policy makers. To define a clear and visible role for soil science in such a complex context is not easy but necessary to allow input of relevant soil science expertise. Two suggestions are made here to strengthen this role. The *first* relates to three ways in which soil can be considered: (1) as an object to be studied with quantitative scientific methods ("it"); (2) as considered by society, expressed, for instance, by rules and regulations or by shear beauty ("we"), and (3) as viewed by the person studying the soil ("I"). Communication by soil scientists to larger groups often suffers when the three approaches are mixed as when personal feelings overly influence scientific study or by whatever society wishes to hear or feels. Being aware of these three views may help to make communications to the outside world more effective (Bouma, 2005). The *second* suggestion relates to the recently introduced

Soil Protection Strategy of the European Union (Commission of the EC, 2006) containing, in turn, two important suggestions: first, it defines seven soil functions that are crucial for land use, and second, it defines the DPSIR approach as a means to characterize soil dynamics. The DPSIR system defines the drivers of land use change (D), the associated Pressures (P) their impact (I) and Response (R) and the subsequent state of a given landscape (S). The seven soil functions are as follows: (1) production of food and biomass; (2) storage, filtering, and transformation of compounds; (3) habitat for living creatures and gene pool; (4) physical and cultural environment; (5) source of raw materials; (6) carbon pool; and (7) archive of geological and archeological heritage. (Note that the term soil, used in the strategy, is equivalent to the term "land," as used in this chapter.) Focusing soil research on these seven functions and consideration of the DPSIR approach can help to clarify and focus the role of soil science in the teams studying the issues mentioned above, all relating to sustainable development (Bouma, 2010). The next question is how to apply this in terms of defining exploratory procedures to obtain options for land use, as discussed in Section 34.4.

34.5.3 Defining Options for Future Land Use

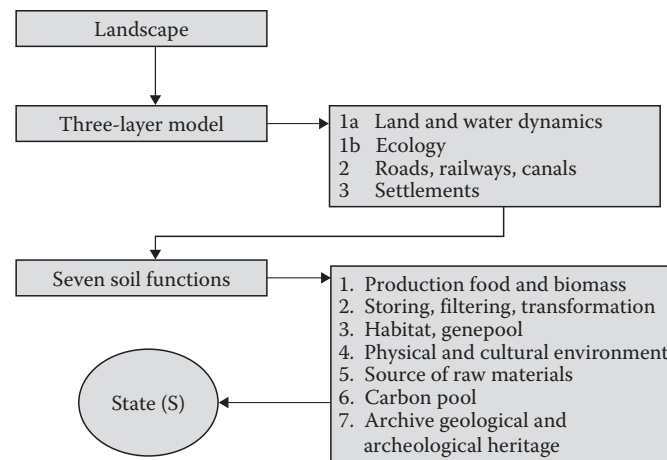
A scheme (Figure 34.3) was introduced by Bouma et al. (2008) allowing the systematic characterization of the state (S) of a given landscape for which a land evaluation is to be made. First it is important to broadly characterize the area in terms of land and water dynamics and ecological conditions. This can be done at K2 level. Hydropedology is a relatively new research activity within the soil science community and is very helpful in this context (Lin et al., 2005, 2006). Also, mapping locations of roads, railways, and canals, as well as settlements, helps to define the context in which the land evaluation will take place. Next, the


FIGURE 34.3 Flowchart indicating how the state (S) of a given landscape can be characterized by systematically considering the three-layer model and the seven soil functions.

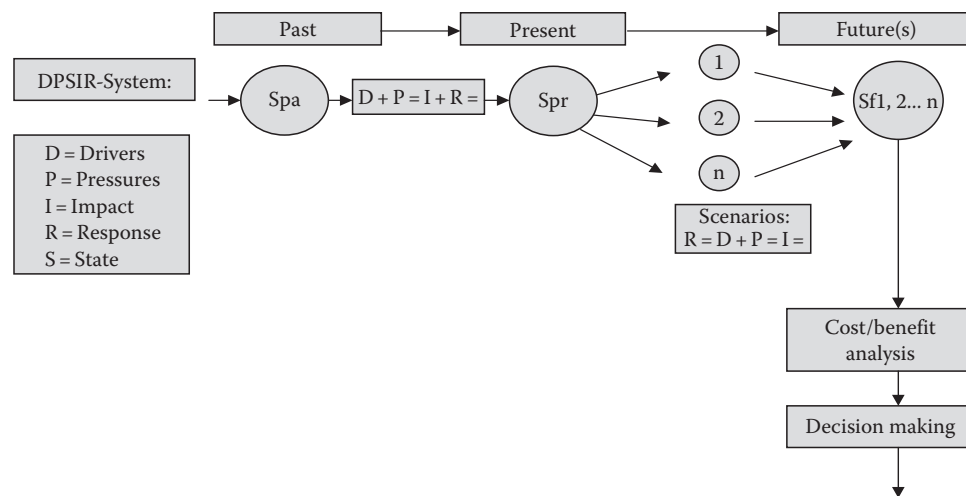

FIGURE 34.4 Illustration of the DPSIR procedure, illustrating how the past (Spa), current (Spr), and future states of landscapes (Sf1, 2, …, n) can be derived from considering D(rivers), P(ressures), R(esponses), I(mpacts), and R(esponses).

seven soil functions are systematically analyzed for the area, where, again, a selection has to be made of the level of knowledge to be applied for each function (see Section 34.5.1). The next step is to put this scheme in a time frame in terms of past, present, and future, where the latter is important for defining land use options as discussed in Section 34.4. Figure 34.4 illustrates the procedure. Drivers for land use change in the past and the associated pressures have led to certain impacts and responses. Effects of selected future options or scenarios are made visible by the responses to drivers and pressures of land use change that are associated with each option. As stated in Section 34.4, options are derived by discussions with stakeholders and policy makers.

34.5.4 Considering the Policy Cycle

Figure 34.4 could suggest that options derived are just presented to stakeholders and policy makers asking them to make a selection of the most attractive one. Even though the procedure of

deriving the various options involved interaction with stakeholders and policy makers, it is important for researchers to more strongly involve both types of users. Again, as discussed above, the success of any land evaluation will in the end be measured in terms of successful acceptance of whatever was created in the procedure. This requires substantial involvement over time. Bouma et al. (2007) have illustrated this by emphasizing the need to consider the policy cycle in planning the research process. This includes various phases:

1. Signaling of a problem, preferably based on a characterization of the current state S.
2. Designing, involving development of options, as discussed above.
3. Deciding: Here, scientists should keep their distance. They design but do not decide. Still, it can be quite effective to give some advice at the right time to keep the decision process moving along.

4. Implementing: Here, researchers have a more distant role, but when they are still involved at this stage, they can answer questions, make minor modifications if certain assumptions turn out to be incorrect, etc. We see many examples where nice options for land use have been derived but where the implementation fails in ways that could have been avoided.

5. Evaluation: Very important for all involved stakeholders including scientists as a learning opportunity.

When dealing with land use issues in land evaluation, scientists often restrict themselves to the design phase (2). To make sure that land evaluations have a real impact in society, we advise the broader involvement described here. Various examples are presented and discussed by Bouma et al. (2007) and Van Latesteijn (1995). Of course, the design phase will remain the core activity and to not become overstretched as a scientist is a real challenge. This calls for a certain division of responsibilities within the scientific community, corresponding with the particular abilities of each member of the team in dealing with various aspects of the policy cycle. In this context, Bouma (2005) proposed establishment of so-called *Communities of Scientific Practice*.

34.6 Operational Procedures

34.6.1 Three Basic Steps

The role and function of soils in a given region, following the approach indicated in Figures 34.3 and 34.4, will become clear when the proper research procedure is selected. This procedure includes three basic steps:

1. Problem definition in interaction with stakeholders and policy makers, resulting in a number of alternative options for land use that are expected to solve problems being identified. The problems are also interpreted in terms of what they mean for the seven soil functions. All functions are not necessarily relevant for each land area, but it is wise to analyze them all. The level of analysis (K1–K5) depends not only on the relevance of each function but also on data availability.

2. Selection of research methods to broadly characterize the land and water dynamics and the soil functions; again, implying a selection in the range K1–K5. This selection not only includes basic data but also simulation models of varying kinds. If not enough data are available, new research can be proposed and initiated. It is attractive to define research needs on the basis of an analysis of shortcomings that would result when using available data only as this is more convincing than research needs that are defined out of context. Attention should be paid to the accuracy and reliability of the various procedures to allow an overall risk analysis in the end, which should, ideally, be an integral part of each land use option being devised (Heuvelink, 1998).

3. Effective presentation of results using modern communication technologies to be focused on prime user groups and policy makers and an evaluation of impacts, including lessons learned.

When performing land evaluation procedures, including an analysis of past drivers of land use change (Figure 34.4), one should realize that there has been a shift in focus during the last decades. Exclusive emphasis on food production and food security after the Second World War has resulted in a technology explosion: problems in food production were there to be solved. Land that was too wet was drained; land that was too poor was fertilized, even at very high rates; land that was too dry was irrigated; and land where crops were suffering from pests and diseases was treated with biocides. Initially, these measures were taken with only food production in mind, and this has led to considerable pollution of land and water locally. Later, concern for the environment played an increasingly important role, and as this process was unfolding, and as a balance had to be struck between agricultural production, on the one hand, and environmental quality of soil and water, on the other, the importance of agroecological features of the land increased dramatically. There used to be the technology-driven spirit: anything can be done anywhere. Now one realizes again that a sand will never be a clay and that the natural dynamics of soils in different agroecological zones are the basis for developing sustainable production systems that are in harmony with natural conditions and the environment.

It is, of course, important to realize that soils do not occur in random patterns in a landscape. Soil scientists know this but the general public and many of our scientific colleagues are hardly aware of this. There is too much talk about "Soils" and "Land" in general terms while, for example, there are 1500 soil types in the Netherlands alone. Much work in soil science has been done on soil classification, grouping soils that are comparable in their basic soil properties. Such groupings are used to describe soil behavior in terms of suitability for a given use (see Section 34.2). But the procedures, illustrated in Figures 34.3 and 34.4, allow extension of this limited approach toward defining characteristic: "windows of opportunity" for any given soil series (which is the lowest hierarchical unit of classification). Different forms of management will lead to different soil conditions within the same soil series, the range of conditions (the window) will be characteristically different for each series. Note that in soil classification, the effects of management have always been ignored for the simple reason that classifications should be more or less permanent and should not change as a result of normal agricultural management. But, in contrast, for land use and land evaluation, the effects of management are very important and need therefore to be associated with the classification.

34.6.2 Considering Effects of Management: The Phenoforms

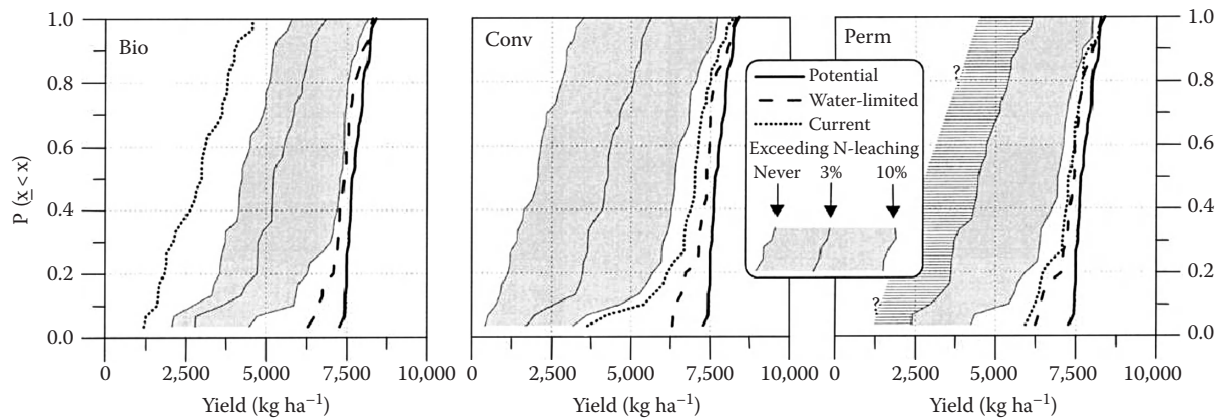
Droogers and Bouma (1997) studied a prime agricultural soil in the Netherlands (a fine, mixed, mesic Typic Fluvaquent according to Soil Survey Staff, 1998). They suggested the terms genoform for the genetic soil name and phenoform for the management variant, of which three were studied, one resulting from 60 years of organic farming (BIO), one from modern intensive arable farming (CONV), and one from continuous grassland (PERM).


FIGURE 34.5 Cumulative probability function of simulated yields for the defined scenarios (see text). Probabilities were obtained by using 30 years of climatic data and are expressed for three probabilities that the threshold for nitrate leaching are exceeded. (Reprinted from Droogers, P., and J. Bouma. 1997. Soil survey input in exploratory modeling of sustainable soil management practices. Soil Sci. Soc. Am. J. 61:1704–1710. Soil Science Society of America.)

They used the validated WAVE model (Vanclooster et al., 1994) to calculate crop yields for wheat as a function of a wide range of N fertilization scenarios. By using yield calculations for a 30 year period with a wide range of weather conditions, they could express both yields and NO_3^- leaching to the groundwater in probabilistic terms (Figure 34.5). This, in turn, allowed the identification of a soil quality indicator for yield-expressing effects on the environment and risk. This indicator was defined by dividing actual calculated production (×100) by potential production where the latter is characteristic for each agroecological zone (Bouma and Droogers, 1998). Pulleman et al. (2000) applied the genoform/phenoform concept to the same soil series and after studying 50 fields, they derived a surprisingly robust regression equation, relating the organic matter content of surface soil (SOM) to previous land history as follows:

$$\text{SOM (\%)} = 20.7 + 29.7\ C_p + 7.5\ C_c + 7.5\ M \qquad (34.1)$$

where

C_p is the past crop type (31–63 years ago)
C_c is the current crop type (1–3 years ago) with grass = 1 and arable = 0
M is the management type (3–7 years ago) with organic = 1 and conventional = 0 ($r^2 = 0.74$)

Sonneveld et al. (2002) found a similar relationship for a common type of sandy soil in the North of the Netherlands, a coarse loamy, siliceous, mesic plagganthreptic alorthod (Soil Survey Staff, 1998) where soil organic carbon (SOC) was related to land use as follows:

$$\text{SOC (\%)} = 3.40 - 1.54 \times \text{Maize} + 0.19 \times \text{Old} + 0.55 \times \text{GWC} \qquad (34.2)$$

where

Maize is 1 for continuous maize, otherwise 0
Old is 1 for old grassland, otherwise 0
GWC is groundwater class in which 1 for class VB and 0 for the dryer class VI

Distinguishing well-defined phenoforms of existing soil series can be quite effective in extending the use of existing soil survey interpretations. Such effects are of major interest to many users and also define a meaningful new and innovative field procedure once the systematic soil mapping of land has finished, as is the case in many countries. Moreover, these findings illustrate the need to view soils as continuous spatial bodies that respond to land use.

This approach can be used at different scales once a database is filled with a number of phenoforms for any given soil series. Larger landscape units on small-scale maps, such as soil associations, are still defined in terms of their internal composition, for example, 30% soil series x, 50% series y, and 20% series z. Then, the effects of different types of management on yield and environmental side effects can still be expressed in a probabilistic manner, be it nongeoreferenced. Also, the fact that mapping units in the field may have quite some internal variability should be considered when making interpretations (Mausbach and Wilding, 1991; Bouma et al., 1996b; Young et al., 1997). The current development of digital soil mapping techniques, using, for example, gamma-ray spectrometry, does open up new possibilities for mapping soil properties at high spatial resolutions for relatively large areas.

34.7 The Crucial Importance of Effective Interaction with the Stakeholders

Interaction with stakeholders has been emphasized many times in the above sections during problem definition and the research process including final reporting. In the past, much research has been top down and supply oriented, which has led to the failure of several development projects (FAO, 2007). The researcher had an impression as to what the problem was that needed to be investigated, and he or she pressed forward using a favorite model, expert system, or data-gathering technique. In the end, the results of the study were presented to the stakeholders.

For sure, there are many examples of fine and effective research being executed in this way that have led to successful implementation. However, there are also too many examples of research efforts that were less successful, ending up in a desk, covered with dust. The challenge, now, is to involve stakeholders to the extent that research is being executed jointly with frequent interaction, with the desirable effect that the end result of the work is experienced as a joint product. This is easier said than done, and it may take a lot of time as illustrated by Bouma et al. (2008) for a regional study of environmental quality in the Northern Frisian Woodlands (NFW) in the Netherlands (see Section 34.8.5). Necessary interaction with stakeholders and policy makers during the research process is not only time-consuming but also potentially perilous. Any researcher has the obligation to make independent studies, whether or not potential results are liked by the stakeholders or not. If he or she gets too involved, objectivity may indeed suffer. This is a reason for many scientists to avoid interaction altogether. Though understandable, it is unwise certainly in the area of land use research that is so strongly tied to societal concerns (Bouma, 2009).

Modern information technology has an important role to play in stimulating interaction with stakeholders. Visualization of alternative land use patterns associated with different options is a very powerful tool to involve stakeholders. A picture says more than a thousand words. Interactive computer technology allows, for instance, instant generation of alternative land use scenarios with all associated input data by researchers and stakeholders. Also, the mentioned improvement of results when moving from K2 to K3, K4, and K5 approaches can be visualized as well by showing the accuracy of the land use maps obtained (Bouma, 1997b). The stakeholder can decide whether or not the costly improvement of the product is worth the cost. As Bouma (1993) has pointed out, several problems can be solved well with a relatively cheap K2 approach based on soil survey reports. This may be scientifically less challenging, but it is important from a practical point of view.

34.8 Case Studies

Six case studies will be discussed covering three spatial scales: the farm, the regional, and the world level. The three steps in the research procedure, as described in Section 34.6, will be followed for each case. Cases will be reviewed broadly, and reference will therefore be made to more detailed source publications.

34.8.1 Precision Agriculture: Arable Farm in the Netherlands

34.8.1.1 Problem Definition and Associated Soil Functions

PA is receiving increasing attention because fine-tuning of the application of fertilizers and biocides to the temporal needs of plants within spatially variable fields can be attractive from both an economic and ecological point of view (CIBA Foundation, 1997). By not applying more chemicals than are used or necessary, costs and losses to the environment are minimized: a "win-win"

proposition. Prime agricultural lands in alluvial deposits all over the world are stratified. Sandy and more clayey spots alternate at small distances. Also other soils, for example, those formed in glacial deposits, may be quite heterogeneous. In this study, precision fertilization and application of biocides were tested in an operational farm setting to help fine-tune management with the objective of maximizing production while minimizing adverse environmental side effects, particularly nitrate and biocide pollution of groundwater. Research results from the past, as reflected in current fertilization advice by extension services, cannot be used for this fine-tuning as they base their advice on simple and highly generalized input-response functions derived from many different plot experiments under undefined environmental conditions. Also, the fertilizer advice implicitly assumes fields to be homogeneous. Existing exploratory or reconnaissance soil maps cannot be used either because they are not detailed enough to characterize fields. A more fundamental problem is the fact that pedological differences, even when expressed on large-scale soil maps, do not necessarily correspond with functional differences in terms of nutrient and biocide transformations, as defined by soil function 2. Functional characterization of soil is therefore a key element of PA as it is "translated" into so-called management units for the farmer, each of which requiring particular treatment in time. Their boundaries do not necessarily correspond with those of mapping units on soil maps. In all of this, aside from function 2, function 1 is crucial, while function 6 may become important as increasing the organic matter content by management in the long run will improve functions 1 and 2 (see Section 34.5.2).

34.8.1.2 Method Selection and Results

The need to define N dynamics and biocide adsorption in soil in relation to crop development requires the use of a quantitative mechanistic K4 model. More empirical and qualitative approaches are inadequate because environmental regulations are strict, and research results are only convincing when obtained at least K4 level. The WAVE model was therefore applied (Vanclooster et al., 1994). Even though a complete 1:50,000 soil map is available for the Netherlands, we lack the necessary detailed 1:5,000 maps to identify differences within individual fields. Besides, the concept of representative soil profiles is used for mapping units even on such large-scale maps and individual borings taken during mapping are not georeferenced. We therefore decided to do a new detailed soil survey for the 110 ha farm being studied (Van Alphen and Stoorvogel, 2000a). The procedure consisted of (1) detailed soil survey; (2) using geostatistics to estimate optimal boring distances; (3) making the soil borings; (4) performing simulations for each boring in the context of functional characterization, leading to the definition of management units to be used in precision management. Pedotransfer functions were used to obtain physical parameters for the simulation model, by relating them to basic soil characteristics (Van Alphen et al., 2001), and (5) perform simulations for each boring on the adsorption of various biocides being used in practice. Functional characterization (point 4 above) is based on items that are relevant for the particular arable system being studied and is site specific. In this case,

four items were relevant to characterize N dynamics: (1) water stress in a dry year, (2) N stress in a wet year, (3) N leaching from the root zone in a wet year, and (4) residual N content at harvest in a wet year. Simulations of N dynamics were made for each boring, and management units were derived with fuzzy clustering and kriging interpolation techniques (Van Alphen and Stoorvogel, 2000a, 2000b). Calculations for three biocides were also made for each point with the WAVE model, focusing on simulated leaching values and associated risks. Patterns of leaching risks for each biocide were obtained by interpolation. Here, the management units, derived for N fertilization, were not used (Van Alphen and Stoorvogel, 2002). The operational farm system for PA consisted of real-time daily modeling with WAVE, using weather data. The stock of nitrogen in the root zone was tracked by calculated crop uptake and leaching as a function of time. As soon as a threshold was reached, the farmer was advised to fertilize. This moment is different in each different management unit (Figure 34.6), as the water and nutrient dynamics are different, even though the weather is identical. Unit 1 needed three fertilizations, and unit 3 needed four. The PA system reduced the amount of applied fertilizers with 25% as compared with the existing system based on generalized functions and resulted in significantly less leaching (Van Alphen and Stoorvogel, 2000b). The biocide studies showed significantly different risks being associated with using the different biocides, and the farmer was advised to use certain biocides only in certain parts of the farm, while using expensive biocides only in parts where risks were particularly high (Van Alphen and Stoorvogel, 2002).

34.8.1.3 Impact and Lessons Learned

This study on PA clearly showed the significant impact of fine-tuning the application of fertilizers and biocides to the varying needs of the plant in time. The soil science focus of this study is rather unique. Much PA work focuses on using remote or proximal sensing to establish crop conditions and to define management units. There has been much progress in developing these sensing techniques. For example, the N status of crop leaves can be well established by now. However, fertilization is already too late when applied after observing a low N status of plant leaves:

growth retardation has already occurred. The soil-focused procedure, illustrated above, provides a signal before the N supply is too low, leading to N stress in the plant. It also allows estimates of possible leaching of nutrients, which is, of course, not possible with remote sensing. A second very powerful thrust in the PA research arena is the technical focus, developing global positioning systems (GPS) equipment and machinery allowing PA procedures. Unfortunately, the various approaches have not been combined and integrated well enough and that is one of the reasons that PA has not been adopted as widely as one would have expected and as one would wish. One lesson learned is that results from soil-centered studies have to be communicated more effectively to provide a counterweight to one-sided commercially motivated approaches by other disciplines. Finally, the soil studies, briefly reviewed above, were only possible thanks to the rapid development of information technology and computing power. As such, this offers unique and quite attractive new opportunities to "assess the performance of land" as required in land evaluation. Here, no abstract judgment is given as to how suitable a soil might be for a given use, but an operational procedure is presented for a farmer that can help to reach the potential of any given soil within commercial units of production, such as fields.

34.8.2 Precision Agriculture: Banana Finca's in Costa Rica

34.8.2.1 Problem Definition and Associated Soil Functions

Where European agriculture is being dictated by a plethora of legislation controlling agricultural management at the national and European level, institutional infrastructure to enforce legislation is lacking in most tropical countries. Despite the fact that national legislation is minimal, the producers of export crops are increasingly being constrained by the importing countries. A good example is the international banana sector in Costa Rica. Costa Rica provides over 25% of the bananas consumed in Europe. Banana producers are influenced in several ways by the market: (1) The European Union has supported the banana production in African, Caribbean, and Pacific (ACP) through

FIGURE 34.6 Management units for a Dutch arable farm with real-time simulations for soil available N contents for management unit 3 (line; kg nitrate-N ha^{-1} in the top 60 cm) and crop N uptake rate (dots; kg N ha^{-1} week^{-1}).

a complex tariff quota system restricting imports from, among others, Costa Rica; (2) the use of biocides is constrained by the regulatory agencies in the United States and Europe. They determine which pesticides are allowed and how they can be applied; (3) a plethora of different labels have been developed in Europe and the United States focusing on chemical use (organic bananas), social production conditions (fair trade), and the environment (ISO 14001, the environmental management standard); (4) in many cases, producers have to follow the guidelines of these labels to be able to export; and (5) large buyers of bananas (e.g., supermarket chains) force the banana plantations to produce under a detailed tracing and tracking system. Given the above, it is clear that the production has moved away from the small farmer. Currently, bananas are produced at large plantations that are either owned by independent producers (50%) or multinational companies (50%). All producers are organized in the Costa Rican Banana Corporation (Corbana). The banana producers have to operate in this complex set of political conditions. That does not only require management adaptations, it also requires the development of alternative management strategies and coordination among producers. Already in 1992 when the environmental lobby pushed hard on the banana sector, Costa Rican producers organized themselves in the Environmental Banana Commission aiming at the improvement of the production system in a more environmental friendly way. Before a plantation can be established, a land suitability assessment has to indicate that the land is suitable for banana production. As a result, Costa Rican banana production takes place under very favorable conditions. One of the plantations, the Rebusca plantation, has been very innovative in the past and maintains close links to the research department of Corbana. The Rebusca plantation is located in the perhumid lowlands in the northeast of Costa Rica (10.5°N, 84.0°W). The plantation measures approximately 124 ha of which 111 ha is used for the cultivation of banana. Like many plantations, the plantation exhibits significant soil variability with soils ranging from Typic Udivitrands to Andic Eutropepts and Typic Dystropepts (Soil Survey Staff, 1998). Like most Costa Rican banana plantations, the production of bananas is intensive with high use of agrochemicals in terms of fertilizers (2400 kg ha^{-1} year^{-1}), fungicides (48 aerial applications per year), and nematocides (3 applications per year). During the last decade, Rebusca has exported through different production channels ranging from a small exporting company owned by a few independent producers to sales through multinational companies. In the first case, production techniques were determined by plantation management, and although they had to fulfill European regulations, there was relatively little control. Exports through the multinationals had many more restrictions and controllers frequently visited the plantation. As a commercial enterprise, the first objectives of management are economical and can be described as profit maximization. Nevertheless, the owner of the plantation is also looking at the environment and tries to minimize the use and indirectly the emissions of agrochemicals to the environment. In contrast to other plantations, the owner is seeking innovations in the production system. This can be explained

in part by a vision toward the future where he expects environmental and social regulations to tighten. After confronting the owner with the concepts of PA, the owner was highly interested. He saw major advantages in terms of chemical use efficiency and the registration of production activities. Just like the previous PA case, the focus is on soil functions 1 and 2 to produce efficiently with minimum losses to the environment.

34.8.2.2 Method Selection and Results

An integrated system for PA was developed for the Rebusca plantation. A detailed description of the system and the process of implementation is presented in the study by Stoorvogel et al. (2004c). In contrast to common practices in PA, we could not make use of standard yield mapping techniques. In addition, the technological focus of PA was not easy adoptable in a continuous cropping system with almost no mechanization and managed by manual labor. Banana plantations in Costa Rica are frequently (2–3 times per week) screened for bunches ready for export. Bunches are harvested and transported by a dense cable system (every 100 m) to the packing plant. For yield monitoring, groups of bunches are coded based on their origin (cable number and the location within the cable). A weighing balance is installed in the main cable just before the packing plant. Codes are registered at the balance, and bunches are weighed. A software package denominated BanMan was developed for data processing and to create and analyze the yield maps. An example is presented in Figure 34.7. In addition to the yield maps, a detailed soil survey has been carried out for the Rebusca plantation Stoorvogel, J.J., Kooistra, L., and Bouma, J. (1999). Spatial and temporal variation in nematocide leaching, management implications for a Costa Rican banana plantation. In: Corwin, D.L., Loague, K., and Ellsworth, T.R. (eds.). Assessment of non-point source pollution in the Vadose Zone. Geophysical Monograph 108. p. 281–289. Key element in an effective system for PA is the translation of site-specific soil and production data into management recommendations. There is an increasing call for the use of crop growth simulation models. However, we have to realize that for many tropical crops, these simulation models do not exist. In this case, we analyze the yield maps in relation to the soil conditions and determine the location of so-called problem areas. These areas are characterized by a relative low production compared to the average production for areas with similar soil conditions. This is an important signaling function after which more detailed studies have to pinpoint to the exact causes of the low production and management can intervene. In addition, fertilizer experiments were carried out on the three main soil types in the plantation where during a period of a year 1 ha blocks received 75%, 100%, and 150% of conventional fertilization. In these blocks, crop performance as well as nutrient leaching was monitored. Depending on the soil type, changes in fertilization resulted in changes in production and/or nutrient leaching. Results for the three main soil types are presented in Table 34.3. In soils 1 and 2, almost all of additional nitrogen is taken up by the plant if we move from 75% to 100% fertilization. However, further increasing fertilization resulted in increased leaching.

TABLE 34.3   Nitrogen Concentrations in Soil Water

Soil	Treatment (%)		
	75	100	150
1	3.61	3.81	4.96
2	4.12	4.08	6.36
3	1.91	2.34	3.29

In soil 3, however, leaching already increased moving from 75% to 100% (with a stable production) indicating that fertilization could be reduced. The low production was caused by the heavy soil textures, poor internal drainage, and low pH. These results formed the basis for site-specific fertilizer recommendations. The recommendations resulted in a decrease in fertilizer use of 12%. An important new development in banana management has been the renovation of areas that experience a decline in production and for which no clear cause can be identified. Often, the deterioration of the plants has been given as the main cause. Due to the site-specific yield monitoring, we can accurately identify the areas that may improve through renovation.

34.8.2.3 Impact and Lessons Learned

The experiences with PA in the banana crop have been very favorable. Farm management has been able to improve the productivity of the plantation, and it has provided them with an improved insight into the performance of the plantation. In addition, they are equipped with an excellent system for the registration of farm management and productivity to answer questions in terms of tracking and tracing. Since the concepts of PA have been introduced in the Costa Rican banana sector, many companies and plantations have used particular elements of PA. A good example

is the site-specific application of nematocides in those areas where nematode concentrations exceed the threshold of 16,000 per 100 g of roots. However, the spatial variation in nematode populations makes sampling and detection an awkward practice. The success of PA at the Rebusca plantation can be attributed to the integrated approach in which all the elements of the cropping system are included and the intensive involvement of the owner of the plantation in the development and implementation phase. Currently, the banana sector is under heavy pressure. Corbana recognizes the value of PA and starts to link their extension work to PA. The strategy of Corbana is that the sector needs to take a proactive approach. Tighter regulations with respect to the environment, the social conditions of workers and tracking and tracing are to be expected and the plantations have to be well prepared. This study presents a high-tech, interdisciplinary approach, developed in close and continuous interaction with the banana growers, to the "assessment of the productivity of the land." In fact, this PA system, operating in a developing country, functions much better than PA systems in so-called developed countries.

34.8.3 Organic Farming in the Netherlands

34.8.3.1 Problem Definition and Associated Soil Functions

The need to create sustainable agricultural production systems that are economically feasible, ecologically acceptable, and socially attractive has led to much discussion in society as to the possible effects of introducing alternative farm management systems. Many of these discussions have an ideological character. For example, to some, organic farming serving regional markets presents a unique road to sustainable development.

To others, industrialized agriculture with a global perspective offers better perspectives. Obviously, this type of discussion is beyond the scope of this text. It is, however, of interest to see if and, if so, how soil conditions may change as different management practices are followed in a given type of soil. This way soil scientists can have independent input into broad discussions on sustainable development. This line of thinking is different from the classical one followed in soil survey interpretations where each soil series is defined in terms of a number of use limitations for a variety of land uses, implicitly assuming that soil properties within a given soil series remain the same, independent of use. To assess the effects of management on soil properties of a given soil series, representing prime agricultural land in the Netherlands, we compared soil conditions on an organic and a conventional arable farm. In contrast, also permanent grassland was added as a variant (Droogers and Bouma, 1996, 1997; Droogers et al., 1996). Several soil functions (Section 34.5.2) are relevant here: (1) biomass production, (2) transformations in the soil, (3) habitat and gene pool, and (6) acting as a carbon pool, function (4) does to a certain extent relate to organic farming as this tends to better preserve the local traditional character of the land as compared with industrial agriculture.

34.8.3.2 Method Selection and Results

Soil conditions can be well expressed in terms of land qualities (FAO, 1976; see Section 34.2.1), which are the moisture supply capacity, nutrient supply, trafficability, and workability, representing a K2 approach. This, however, is descriptive and not diagnostic. We, therefore, decided to use a deterministic, quantitative K4 model (WAVE; Vanclooster et al., 1994) that allows quantitative characterization of soil moisture regimes and associated N transformations. Common soil properties such as bulk density, porosity, moisture retention, and hydraulic conductivity reflect the effects of short-term management. Tillage or soil traffic under wet conditions or poor management may in a given year lead to compaction, puddling, and structure degradation, which may not occur in the same soil where soil traffic is avoided or where the farmer does a better job. We, therefore, focused here on soil properties that are not significantly influenced by short-term management such as the organic matter content, which is affected by long-term management in terms of decades. Moisture retention and hydraulic conductivity data needed to be measured because estimates with pedotransfer functions could not be made as they did not cover the range of organic matter contents observed. To adequately represent the effects of different contents of organic matter on N mineralization, we measured rate constants to be used in the N module of WAVE. Thus, a relatively high data demand materialized. Simulation runs were made for 30 year periods using real weather data, allowing expressions of production and leaching of NO_3^- in probabilistic terms. Predictions of moisture contents in surface soil allowed estimates to be made for trafficability and workability (Droogers et al., 1996). Runs for 1995 were compared with measured data, showing that the model performed satisfactorily. Validation was thus assured, but no thorough sensitivity or error propagation analysis was performed.

Results were presented in graphical form. The increased organic matter content originating from organic farming resulted in a 20% increase of potential productivity (Droogers and Bouma, 1996, 1997). However, trafficability and workability decreased because the higher moisture contents during the year resulted in shorter periods with adequate trafficability and workability (Droogers et al., 1996). Indeed, strong compaction was observed in fields of the organic farm where conventional plowing to 30 cm depth was used. We also addressed the question as to how production and NO_3^- leaching could be balanced, using a probabilistic graphical expression (Figure 34.5). This graph was also used to define soil quality in terms of production and leaching of NO_3^-, illustrating that the user must choose the level of risk he or she is willing to take. This risk relates to yields (probabilities that a certain yield is exceeded) and to NO_3^- leaching (probabilities among the years that the threshold value for NO_3^- leaching is exceeded).

34.8.3.3 Impact and Lessons Learned

Organic farming resulted in higher organic matter contents that, in turn, allowed higher potential productions because of a higher water supply capacity. However, risks of causing structure degradation were higher as well, and it was shown clearly that traditional plowing to 30 cm depth did indeed result in such degradation. We advised to explore minimum tillage as an alternative tillage practice, and this was followed up by the farmers. This study also led to the initiation of a broader study relating past land use successfully to organic matter content of surface soil, as reported in Section 34.6.2 by the study of Pulleman et al. (2000). The K4 land evaluation approach followed in this chapter is a far cry from the traditional K2 procedure. But it still focuses on the central issue of land evaluation, that is, "the assessment of land performance when used for specified purposes," as it addresses real questions of the land user. Computer simulations for a series of years allow expressions in terms of risks, and this is important: scientists do not only provide a verdict as to the suitability of a given form of land use but define risks associated with particular actions. It is up to the land user to decide what to do based on the risks he or she is willing to take. One lesson learned was the fact that this study defined a welcome "niche" for soil science in the very broad and often emotional societal discussion about sustainable land use and the role of organic farming. Looking back, we should have pursued this approach systematically for other major soil series offering a model for post soil mapping research. In fact, this type of work was done later only for a major soil series in sandy soil (see Section 34.6.2).

34.8.4 Alternative Land Use in Ecuador

34.8.4.1 Problem Definition and Associated Soil Functions

Although the commercial farmers of the Carchi region in Northern Ecuador are probably some of the better endowed in the rural communities of the Andes, it became increasingly apparent that the use of pesticides in intensive potato production

was not only a blessing but a curse as well. In the early 1990s, researchers, farmers, and NGOs paid increasing attention to the negative effects of the intensive use of pesticides. The farmers in the Carchi region were very much dependent on these pesticides to control pernicious pests and blight. Intensive on-farm research revealed some of the major health and environmental impacts associated with these pesticides. The intensive use of highly toxic pesticides resulted in significant neurobehavioral effects on farmers, and pesticides were detected in groundwater as well as streams that serve irrigation and domestic use downstream. A broad signaling phase with large groups of stakeholders, however, also drew the attention to soil erosion. Many fields revealed the light-colored subsoil on the upper parts of the fields, and the common perception was that water erosion was the main cause. However, research showed that water erosion was not responsible for the erosion of the topsoil due to low rainfall intensities in combination with a high infiltration capacity of the volcanic ash soils. The steep fields cultivated with potatoes require intensive tillage. All tillage and harvest operations transport topsoil material down the slope. On fields tilled with tractors, the situation is even more serious. As slopes are too steep for contour plowing, tractors plow downslope. Rather than water erosion, tillage erosion was in this case the main cause for the observed erosion processes. This example clearly shows not only the importance of stakeholder input but also the impact of scientists in the signaling phase, avoiding misperceptions that could easily have led to irrelevant routine research on water erosion. After signaling and quantifying the key sustainability factors, that is, human health and environmental impacts of pesticide use and tillage erosion, the question that remained was how to intervene. Clearly, the reduction of pesticide use and pesticide handling issues were the two elements to focus on to reduce the environmental and health impacts of pesticides. To reduce the impact of tillage erosion, very few technical solutions were available. The potato crop requires intensive tillage, and any tillage practice on these steep slopes automatically results in soil erosion. The only practice that significantly reduces tillage erosion is based on the little-known pre-Columbian limited tillage/cover potato system: Wachu rozado that is still being practiced in Northern Ecuador. In this system, seed potatoes are placed on top of the pasture, and the grass mat is folded over the potatoes.

34.8.4.2 Method Selection and Results

A 2 year dynamic farm survey provided insight into the management decisions of the farmers in the Carchi region. This resulted in an economic simulation model (TOA) allowing for the ex ante evaluation of alternative policy and management scenarios (Crissman et al., 1998; Stoorvogel et al., 2004a, 2004b). The TOA methodology addresses two key elements: first, it provides an organizational structure around which to design successful interdisciplinary research that assesses the sustainability of production systems; second, it provides a successful means to communicate research findings to policy makers and the public. Farmers are the Andes' most numerous and most important soil resource managers. Agricultural technology ranges from traditional, extensive, low-input, low-output systems to modern, intensive, high-input, high-output systems. The traditional systems have to be maintained within their ecological constraints and, as a result, are generally perceived as environmentally friendly and sustainable. However, due in part to shrinking farm size, traditional systems have proven to be economically and socially nonsustainable. With a closed agricultural frontier in most parts of the Andes, the fundamental option for Andean farmers is to increase the physical and financial output from the existing farm. This inexorable pressure provides a strong incentive to shift to the higher output modern systems. The basic quest of agricultural and environmental research for sustainable farming systems is to match the environmental friendliness of traditional farming systems while reaching the higher outputs and, thus, the economic and social sustainability found in modern farming systems. Figure 34.8 shows an example of the type of answer one can expect from the TOA system. The trade-off curves between net returns and carbofuran (one of the most commonly applied highly toxic insecticides) leaching are

FIGURE 34.8 Trade-offs between net returns and carbofuran leaching under two different management scenarios for the potato-pasture system in Northern Ecuador.

constructed by varying the potato prices. In the base scenario, the current management system is evaluated. The trade-off curve shows that with increasing potato prices, the net returns of the systems increase coinciding with an increase in carbofuran leaching. The latter is not only due to an increase in the potato area but also due to a more intensive management of the potatoes. Two alternative scenarios have been evaluated: the effect of tillage erosion and the effect of the introduction and adoption of Integrated Pest Management (IPM). Due to tillage erosion, we see that carbofuran leaching increases. This can be explained by the removal of the organic matter-rich topsoil that fixes carbofuran. IPM shows an opposite effect where the trade-off curve is moving down. Less carbofuran is being applied, and as a result, leaching is going down. However, the reduction of IPM comes at a cost. Alternative management practices are required to control the pest requiring farm labor. As a result, net returns are slightly decreasing.

34.8.4.3 Impact and Lessons Learned

The TOA provided information on possible interventions both at the political level and at the farm level. In various follow-up projects, the policy cycle has been closed. While pesticides have not been eliminated from the Carchi communities, they are now generally used more cautiously. There is also momentum at the policy level for reducing pesticide dependence. In 1999, all stakeholders were brought together to discuss pesticides and health. This meeting resulted in the Carchi declaration demanding the elimination of the highly toxic products, the inclusion of IPM in university level agriculture training, and a wider dissemination of information on the effects of pesticides. In addition, farmer field schools have been set up in which farmers and the research community developed not only IPM technologies but also pesticide handling measures to reduce the impact of pesticides. The effects of various management changes, as part of IPM, on these farmer field schools are striking. The number of pesticide applications was reduced from 12 in conventional plots to 7 in plots with IPM. Even more important, the overall amount of pesticides applied dropped dramatically. The amount of fungicides decreased by 50%, while insecticide quantities dropped between 40% and 75%. The Carchi story is illustrative for a combined effort in which farm surveys, advanced simulation modeling, geographical information system (GIS) techniques, IPM research, stakeholder meetings, and farmer field schools led to a strong reduction of pesticide use in the Carchi study area. It illustrates the strength of the research chain rather than a single method and/or project. The project was successful in designing innovative production systems for potatoes that were environmentally friendly while protecting the health of farmers. Political decisions were made about environmental and health regulations, and they were implemented, so far only at the regional level. Educational programs for farmers were initiated during this research projects and are continued up to this day. This study not only "assessed the performance of land" but also added and integrated crucial economic and social components, which were part of the original definitions of land evaluation but were hardly incorporated in conventional land evaluation studies focusing on land suitabilities and limitations.

34.8.5 Environmental Quality in the Northern Frisian Woodlands, the Netherlands

34.8.5.1 Problem Definition and Associated Soil Functions

Environmental losses from dairy farming systems in the Netherlands are among the highest in Europe. A strong focus on increasing dry matter production though increases in fertilizer N inputs resulted in average N losses of more than 300 kg N ha^{-1} in the beginning of the 1990s. The excessive loading of groundwater and surface water in the past has stimulated the development of environmental policies at European and national level. Especially, the European Nitrates Directive (EC, 1991) and its translation through the Dutch MINAS legislation have had a profound impact on management practices at farm and field level.

The Nitrates Directive has adopted a threshold for the nitrate concentration in the upper groundwater that corresponds with the E.U. drinking water directive: 50 mg L^{-1}. In 1998, the Netherlands introduced the MINAS policy, a budgeting tool for N and P and farm level with a maximum N surplus of 180 kg N ha^{-1} to be reached in 2003 for sandy soils. Dairy farmers in the Friesian Woodlands in the North of the Netherlands were also confronted with high N surplus levels in the 1990s. Provincial groundwater monitoring networks reported nitrate concentrations for this region well above the 50 mg L^{-1} threshold (Sonneveld and Bouma, 2003). A regional nutrient project was initiated by Wageningen University in close collaboration with local farmers to develop and disseminate knowledge on possibilities for reducing N losses and hence increasing N efficiencies at farm level. A need was expressed in 2004 to provide regional policy makers and farmers with information on the quality status of groundwater in the Friesian Woodlands.

A number of land functions (Section 34.5.2) are especially relevant for the question raised: (1) biomass production; (2) transformations in the soil; and (6) acting as a carbon pool, which is specifically linked to land use on the dairy farms. The functions, physical and cultural environment (4) and geological and archeological heritage (7) became relevant in 2004. In that year, the area was designated as a National Landscape, because of the small-scale elongated fields in the area bordered by hedges and a unique high concentration of pingo-remnants from the Weichsel glacial period.

34.8.5.2 Method Selection and Results

The NFWs cover 60,000 ha and occur in the northern part of the Netherlands. Land use consists predominantly of grassland (80%) with some silage maize (5%). The area mostly consists of hydromorphic podzols developed in Pleistocene coversands. The regional nutrient project (Verhoeven et al., 2003) that aimed at lowering N surpluses adopted a strong participatory approach with study groups among farmers and

contributions from scientists from different disciplines (animal science, soil science, and grassland science). Farm management practices and N surpluses were monitored and used for feedback within the study groups. Different methods were adopted to assess nitrate concentrations in the upper groundwater and N and P concentrations in surface waters in the NFW region:

1. The available STONE model was used to calculate N and P losses at regional level. This quantitative model is based on process description and can be described as a K5 model. The STONE model (Wolf et al., 2003) is used to calculate nutrient loads from the soil system to the surface water and groundwater. STONE calculates nutrient fluxes for different forms of land use like grassland, arable land, and nature and nitrate concentrations in the upper groundwater. The region was divided into 398, 250×250 m grid cells for which specific hydrological, soil physical, and soil chemical characteristics could be derived by downscaling existing soil survey maps. All cells are hydrologically separated but are connected to various drainage levels, like ditches, canals, and subsoil. This implies that STONE behaves spatially like a semi-3D model. All cells have a specific soil type and corresponding soil hydraulic characteristics for the unsaturated zone. The P status and mineralization capacity of the soil are also input for the model. In the STONE model, the water balance model SWAP (Belmans et al., 1983; Van Dam et al., 1997) is used to simulate water fluxes, and the ANIMO model (Groenendijk and Kroes, 1999) is used to simulate nutrient dynamics and nutrient transport. In the initial STONE simulations, the amount of fertilization on the 250×250 m grid was calculated based on "downscaled data 2000" of the Dutch national database on manure application and the assumption that mineral fertilizer was used according to the Dutch national fertilization recommendation. The available data represent the situation in the year 2000. In the second STONE simulation, regional data (2004) on manure application and fertilizer use were used ("regional data"), and grid cells of 25×25 m were used to be able to apply the regional data of manure application on the scale of the fields. Data available for farms were allocated to the small grids. Meteorological data on a daily basis are used as input.

2. A regression method was used based on a modeling study for sandy regions in the Netherlands (Roelsma et al., 2003) where nitrate concentrations had been related to autumn mineral N contents in soil (K3 level) was also applied for a selection of 29 farms on sandy soils (Sonneveld et al., 2010a). In general, agrienvironmental indicators that can be used for monitoring by stakeholders are useful in providing learning feedbacks. The following model was applied:

$$NO_3^-[\text{year} + 1] = C + 0.764N_m[\text{year}] - 37.9P \quad (34.3)$$

where

NO$_3^-$ is the nitrate concentration in the upper groundwater in spring

year is a particular year

C is a constant depending on hydrology and soil type

N_m is soil mineral nitrogen (kg ha^{-1}) in autumn for 0–90 cm

P is a dummy for the occurrence of a peat layer (1 = yes and 0 = no)

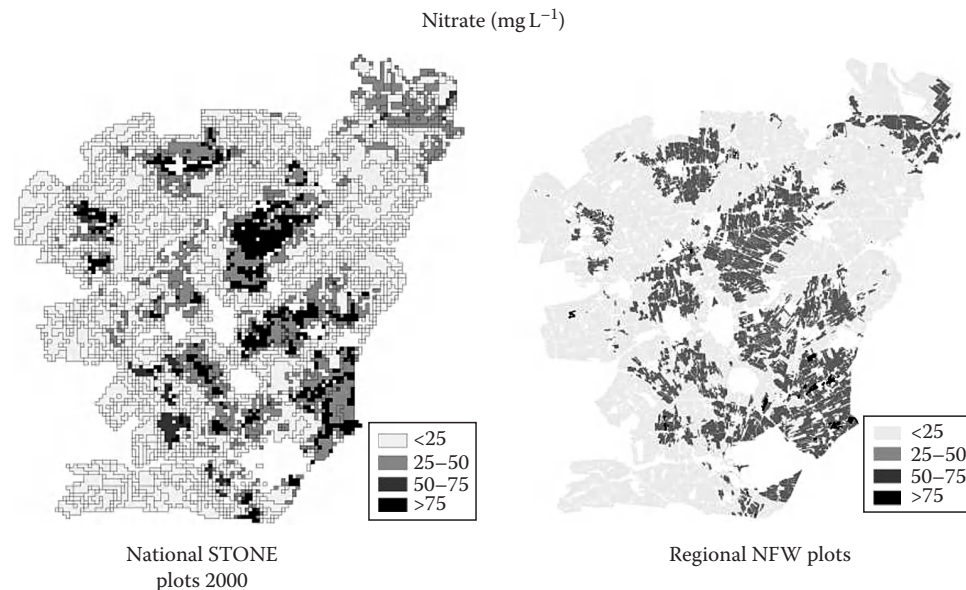
For application of this regression model, a monitoring campaign for soil nitrate contents was performed in the autumn of 2006. This method was introduced to see whether soil mineral N contents could be used as an easy indicator by farmers for assessing nitrate concentrations in the upper groundwater.

3. Finally, to validate the above mentioned K3 model, an intensive monitoring campaign was performed in 2007 on more than 300 locations to measure nitrate concentrations in the upper groundwater. In itself, this can be described as a K4 approach.

N losses at farm level were considerably reduced from 1997 to 2003. In this period, the average N surplus dropped from 327 to 168 kg N ha^{-1} (Verhoeven et al., 2003). The reductions were largely achieved through reduced inputs of fertilizer N inputs and improved efficiencies of manure N. For the years 2000 and 2004, STONE calculated relatively low average nitrate concentrations in the upper groundwater in the area with a mean value for the region of 22 mg NO$_3$ L^{-1} for the "downscaled national 2000 data" and 15 mg NO$_3$ L^{-1} for the "local 2004 data" (Figure 34.9). The estimates are far below the E.U. limit of 50 mg NO$_3$ L^{-1}. However, there is a large variation in nitrate concentrations for the year 2000 ranging from higher values in the drier sandy soils to lower values in the peat soils, which is related to differences in denitrification rates. The results for the year 2004 indicate overall low values.

The regression model predicted average nitrate concentrations in the upper groundwater for 2007 to be around 82 mg L^{-1}, which was much higher than the predictions for 2004 by the STONE model. Predicted 90 percentiles of nitrate concentrations in the upper groundwater using the K3 regression method were >150 mg L^{-1} for farmers on sandy soils. Based on the validation data (the K4 method), however, the estimated 90 percentiles were <50 mg L^{-1}. Several observations with high concentrations were especially found on field with arable cultivation (silage maize). Thus, Sonneveld et al. (2010a) concluded that the regression model based on national data was invalid for this particular region and lead to significantly different conclusions. The field measurements appeared to correspond with the STONE model calculations for the year 2004.

34.8.5.3 Impact and Lessons Learned

The results of the participatory approach used in this nutrient management project gave a strong impetus to involve farmers in searching for possibilities for reducing N and P losses to the environment. The strongly reduced N losses in the Northern sandy


Nitrate (mg L^{-1})

National STONE
plots 2000

Regional NFW plots

FIGURE 34.9 Mean nitrate concentrations in upper groundwater calculated for the years 2000 (a) and 2004 (b).

regions have also been documented in national inventories. The annual environmental report reported that currently, high nitrate concentrations are mainly a problem of southern sandy regions (>80 mg L^{-1}) and not of the northern regions. The STONE model simulations yielded especially relevant results when regional data on land use were introduced in the 2004 model simulations. This strongly suggests that regional calibrations remain a vital component of introducing and applying K5 models at regional scales. The K3 regression models clearly overpredicted nitrate concentrations substantially. It was also found that actual measurements on nitrate concentrations were found to be most convincing for farmers and regional policy makers. Several scale levels were involved in reaching the environmental objectives. Policy formulation at E.U. level resulted in national legislation (MINAS), which was translated to individual farms through a regional nutrient management project. Although national legislation has changed in past years, the insights that were gained have not been lost, and surpluses have continued to decrease over the years. The questions raised clearly went beyond classical land evaluation that is strongly focused on biomass production and follows a top-down strategy. Here, questions did not so much center around options for main types of land use as grassland is considered to be the most important component of dairy farming systems in the region. However, specific management strategies as to how to manage and fertilize pastures (LUTs) were being developed. Options for changing land management practices especially evolved from close collaborations between scientists and farmers and resulted in decreased environmental losses. Model simulations at the regional level as well as field measurements at local level confirmed that the reduced N surpluses resulted in nitrate concentrations <50 mg L^{-1}. Discussions have risen whether the small proportion of silage maize at some dairy farms cannot be replaced with grassland as the higher nitrate concentrations were largely found under fields with maize cultivation.

34.8.6 The World Food Crisis: Assessment of Food Security

34.8.6.1 Problem Definition and Associated Soil Functions

The world population is expected to double by the year 2030. Enough food is produced now, even though its distribution is poor, leaving 800 million people with inadequate food supplies. Many studies have been made on the potential of the Earth to feed its people. We will refer here to the still highly relevant work by Penning de Vries et al. (1995) because they used a modern land evaluation procedure and made some interesting decisions on procedures that correspond to the global level of detail. This study tried to answer questions about global food security by considering three population growth scenarios and two types of agriculture, one with high external inputs (HEI) and the other with low external inputs (LEI). Also, three diets were considered to reflect the demand side: a vegetarian, moderate, and affluent diet. The reader is referred to the above publication for more details on the interesting results of the study. Research at this scale can only be exploratory in a broad sense, and many simplifications are involved. Emphasis was placed on exploring agricultural production potentials. Whether or not these are reached is realistically considered to be beyond the scope of the work as it will depend on socioeconomic and political decisions. What is offered are characteristic windows of opportunity and, as such, the study has led to interesting insights into possible future developments. This study at world level focuses exclusively on biomass production (soil function 1) under a series of conditions relating to management, food consumption, and population growth.

34.8.6.2 Method Selection and Results

A K2 approach might appear to be realistic at first sight. However, no expert can oversee the immensely diverse production

conditions prevailing in different areas of the world. The authors chose, therefore, a K3 approach using a very simple model to calculate crop yields based on available radiation, water, and nutrients. Thus, a universal approach was introduced allowing comparisons among all calculated values. They assigned all possible crops to a cereal (wheat in moderate climates and rice in the tropics) or grass equivalent to obtain a so-called grain equivalent (GE), which makes comparisons relatively easy. The NASA database was used for 1° × 1° grid cells, which occupy a 110 km × 110 km area at the equator. Confining attention here to soils for each grid cell, the authors selected values for slope, soil phase, and soil texture. Selections were based on the 1:5 million FAO World Soil Map and other available data. Clearly, choices were highly arbitrary. Cells often contain different land units, each representing major soil associations with many soil types. Soil texture of the dominant association was applied to the entire cell. Dominant soils in each cell were considered to be well drained, homogeneous without layers or cracks, to be 60 cm deep and without runoff. Degradation of soils was ignored, and so were current land use patterns. For the entire world, 15,500 land units had to be considered along with 700 climatic zones. The model was run for all cells, divided into 15 major regions, which were also distinguished for U.N. population studies, and for different scenarios representing population increase and management types. Estimates for grid cells could have been compared in some areas with estimates obtained using more reliable basic data derived from large-scale soil maps. This, however, has not been done. Therefore, the accuracy of the resulting data cannot be determined, which illustrates the broad exploratory character of the exercise. Still, the alternative is to have nothing at all, and we prefer such a rough estimate, which can be improved upon, over a lack of any estimate.

GIS was used to present maps for the different scenarios, which was effective in communicating the major results of the study. For example, a problem was perceived for Southeast Asia, where food shortages are likely in future even at low rates of population increase and with high-input agriculture.

34.8.6.3 Impact and Lessons Learned

This exploratory study has functioned well to define some major worldwide trends in food security, some of them rather surprising. Food production at the global level can increase significantly, but a strong spatial variability exists. When HEI farming is practiced, all regions can produce the required food, except some areas in Asia. Europe, the Americas, and Central Africa are well-off. Depending on the level of consumption selected, Europe, for example, can grow its food on 30%–60% of its suitable soils and in the America's, this is 20%. When choosing the LEI approach, South Asia will have a food shortage even at the minimum food demand. The impact of studies such as these is difficult to measure. Reports of U.N. agencies have, for example, recently taken a more specific approach to defining food security by focusing on particular regions, and this is supported by the type of studies discussed here. Also, showing the implications of HEI versus LEI management systems in different regions serves

to focus ideological discussions dealing with the most desirable type of farming by presenting plausible consequences of following either HEI or LEI approaches. The study adds an important element to the concept of land evaluation, by including the demand side of the issue of food security. "Assessment of land performance" is not only determined here by the productive capacity as such, which is divided into the LUTs HEI and LEI, but also as a function of demand, which depends on the type of food consumption and on population growth. Thus, land evaluation is placed in a relevant societal context, while the input of soil data is rudimental, to say the least. The tendency of soil scientists is to implicitly assume that the more detailed soil data are provided, the better the land evaluation. The study shows that this is not necessarily true at world level. Unfortunately, soil scientists have not followed up this study by showing what might be gained by improving the soil input data for the model. Finally, one lesson learned is the necessity to repeatedly present studies to a large audience as this work has not received the attention it deserves. The work is not finished when the research report is finished (see also remarks about implementation in the policy cycle in Section 34.5.4).

34.9 New Thrusts for Soil Survey and Land Evaluation

34.9.1 Using New Technologies in the Proper Context

New technological developments are likely to change soil studies in the years to come (see NRC, 2009). Low-cost GPS allow accurate positioning of observers and equipment anywhere in the world. New satellites will strongly increase the opportunity to observe the surface of the Earth in more detail than ever before using an increased number of diagnostic features. Remote sensing from satellites or airplanes will allow better evaluation of crop conditions allowing improved yield predictions. In addition, on-the-go yield monitoring is becoming well established and will revolutionize the assessment of the production capacity of the land by providing a continuous record for many years. In turn, measured differences in yield will give rise to specific research on the underlying causes, which may be many.

Technological developments not only apply to measurements above the soil surface but also to measurements below the soil surface. Many new sensors are being developed to be used for the continuous registration of soil water and solute contents. Already, time domain reflectometry is widely used to measure soil water contents, replacing neutron probes. Transducer tensiometers allow accurate, instant registration of pressure heads in the soil within the range of interest for plant growth. Sensors for N contents in soil are being developed in the context of PA. Information technology allows not only rapid registration but also transmission to central computers. Indeed, some study sites resemble patients in intensive care.

Opportunities to interpret soil data have dramatically increased as well. A wide range of simulation models is available

to predict soil water contents and solute fluxes, even in heterogeneous soils that swell and shrink and may show hydrophobic behavior. This must be calibrated and validated to fit the needs of specific areas where land use questions are raised. Also, expert systems have been perfected allowing a more efficient application of the vast body of knowledge residing with users of the land. GISs, finally, allow integration of different types of data, coupling of databases with models, and construction of digital terrain models with unique opportunities to visualize landscape processes. Interactive use of GISs will enhance effective contacts with end users and policy makers. How will this new technology be used to improve our land evaluation practices? The above case studies already indicated some approaches, but this is only a start. A major challenge for the future is to use this modern technology in a meaningful way keeping in mind the overall objectives of the particular land evaluation being considered. There is a clear risk of a technology push where application of fancy new technologies becomes a purpose in itself. Continued contact with stakeholders and policy makers, as advocated above, is usually quite effective in keeping track of objectives.

34.9.2 Future Land Evaluation Based on Soil Studies

In many, so-called developed countries, standard soil surveys of agricultural lands at scale 1:20,000–1:50,000 have been completed. Revisions of old maps are being made, but funds are often not available to do this. Rather, surveys for specific purposes are increasingly commissioned, or maps are generated using available data that are available in well-accessible databases in many countries. Such data, rather than classical soil maps are then used for a wide variety of applications, using pedotransfer functions and modeling techniques and other means of interpretation. The use of modern GIS software allows rapid generation of flashy reports by nonsoil scientists who are hardly aware of the underlying processes and restrictions to be imposed on data and interpretations being used. Soil scientists should be quite aware of this and make sure that they inject and generate new data as needed to keep their evaluations relevant and up to date. If we only mine existing data, soil science will die (Bouma, 2009). Recent developments in digital soil mapping illustrate innovative state-of-the-art approaches for soil characterization and land evaluation, proving that soil science is still very much alive in contributing to land evaluation in a manner that is highly relevant for society at large now and in the future (Lagacherie and Mc Bratney, 2007; Hartemink et al., 2008).

35.1 Introduction

Hydropedology is an emerging interdisciplinary science that grew out of the need to address complex natural processes in the earth's critical zone (Wilding and Lin, 2006). Increasingly, scientific research is being conducted by multidisciplinary teams as demanded by the complex, dynamic, and spatial–temporal variability of natural systems that require inputs from various disciplines (Sposito and Reginato, 1992). Hydropedology seeks to bridge disciplines to address (1) knowledge gaps between pedology, soil physics, hydrology, and other related bio- and geosciences; (2) scale differences in microscopic, mesoscopic, and macroscopic studies of soil and water interactions; and (3) data translations from soil survey databases into soil hydraulic properties (Lin, 2003).

Hydropedology is a union of hydrology, pedology, and soil physics disciplines with a focus on soil–water interactions. Hydrology is defined as *the science that treats the waters of the Earth, their occurrence, circulation and distribution, their chemical and physical properties, and their reaction with their environment, including their relation to living things* (NRC, 1991). Pedology is defined as *the branch of soil science that integrates and quantifies the formation, distribution, morphology, and classification of soils as natural or anthropogenically modified entities* (Wilding, 2000; Buol et al., 2001; Lin et al., 2006). Soil physics is defined as *the study of the physical properties of the soil and the relation of the soil physical properties to the study of the state and transport of matter and energy* (Scott, 2000). Although these

definitions are specific and cover the breadth of each discipline, water dynamics, response, and the interactions with the environment are common underlying themes. As a need to unite these disciplines, hydropedology has been defined as *an intertwined branch of soil science and hydrology that encompasses multiscale basic and applied research of interactive pedologic and hydrologic processes and their properties in the variably-unsaturated zone* (Lin, 2003). More specifically, hydropedology focuses on the synergistic integration of pedology and hydrology to enhance the holistic study of soil–water interactions and landscape–soil–hydrology relationships across space and time. Its aim is to understand pedologic controls on hydrologic processes and properties and hydrologic impacts on soil formation, variability, and functions (Figure 35.1; Lin et al., 2008b). Even though hydropedology has its foundation in pedology, soil physics, and hydrology, it is also linked to other bio- and geosciences such as geomorphology, geology, geography, hydrogeology, hydroclimatology, ecohydrology, biology, and other branches of natural sciences (Figure 35.2). In a broader sense, hydropedology seeks to identify feedback mechanisms that allow for a holistic approach to the study and prediction of ecosystem functions.

This chapter provides an overview of the fundamentals and applications of hydropedology, including a review of some guiding principles and several recent advances in soil architecture and preferential flow, soil hydromorphology, scaling, digital soil mapping (DSM), pedotransfer functions (PTFs), and coupling biogeochemistry with hydropedology.
FIGURE 35.1 Hydropedology connects the pedon and landscape paradigms through linking phenomena occurring at the microscopic (e.g., pores and aggregates) to mesoscopic (e.g., pedons and catenae), macroscopic (e.g., watersheds and regional), and megascopic (e.g., continental and global) scales. (From Lin, H.S. 2010. Earth's critical zone and hydropedology: Concepts, characteristics, and advances. Hydrol. Earth Syst. Sci. 14:25–45; and Atkinson, T.C. 1978. Techniques for measuring subsurface flow on hillslopes. *In* M.J. Kirkby (ed.) Hillslope hydrology. John Wiley & Sons, Chichester, U.K.)

FIGURE 35.2 A conceptual diagram illustrating the relationship of hydropedology to other related disciplines. (From Lin, H.S. 2003. Hydropedology: Bridging disciplines, scales, and data. Vadose Zone J. 2:1–11.)

35.2 Fundamental Questions and Basic Characteristics of Hydropedology

Two fundamental questions of hydropedology are as follows (Lin et al., 2008b, 2008c):

1. How do soil architecture and the distribution of soils over the landscape exert a first-order control on hydrologic processes (and associated biogeochemical and ecological dynamics) across spatio-temporal scales?
2. How does water at the landscape scale (and the associated transport of energy, sediment, chemicals, and biomaterials by flowing water) influence soil genesis, evolution, variability, and functions?

Water at the landscape scale encompasses the source, storage, availability, flux, pathway, residence time, and distribution of water in the near-surface terrestrial environment. While source, storage, availability, and flux of water in the soil have been studied extensively in the past, attention to flow pathways (especially flow networks), residence time (age of water), and spatiotemporal pattern of flow dynamics (and its underlying

organizing principle) has been much limited (Lin et al., 2006; McDonnell et al., 2007). Two basic characteristics of hydropedology are linked to the above two questions:

First, hydropedology emphasizes in situ soils in the landscape, where distinct pedogenic features (e.g., aggregation, horizonation, and redox features) and soil–landscape relationships (e.g., catena, soil distribution patterns, and soil map units) are essential in understanding interactive pedologic and hydrologic processes. Developing quantitative relationships between complex natural soil architecture and soil hydrologic functions across scales is an important research area of hydropedology. Three related key aspects are as follows:

- Hydropedology calls for a new era of soils research that is based on soil architecture (broadly defined as the entirety of how the soil is structured) that is beyond soil texture alone, so that the prediction of flow (and reaction) pathways, patterns, and residence times can be made realistically. This requires innovative techniques for improved quantification of soil architecture at different scales, especially in situ, noninvasively, and linking such soil architectural parameters to field-measured soil hydraulic properties.
- Hydropedology considers the soil in the real world as a "living" entity in the landscape rather than "dead" material that is manipulative mechanically. As Kubiena (1938) pointed out, a crushed or pulverized sample of the soil is related to the soil formed by nature like a pile of debris is to a demolished building. The full benefit of understanding this living system lies in studying them close to their natural setting in the real-world setting.
- Hydropedology attempts to link the form and function of soil systems across scales (Lin et al., 2006), rather than mapping soils without considering soil functions or modeling soils without incorporating soil architecture and soil–landscape patterns. Jenny (1941) clearly noted at the end of his famous book *Factors of Soil Formation*,

The goal of soil geographer is the assemblage of soil knowledge in the form of a map. In contrast, the goal of the "functionalist" is the assemblage of soil knowledge in the form of a curve or an equation… Clearly, it is the union of the geographic and the functional method that provides the most effective means of pedological research.

- Such a union of soil maps and soil functions is what hydropedology hopes to promote in quantitative ways.

Second, hydropedology deals with the variably unsaturated zone in the terrestrial near-surface environment, including the shallow root zone, deeper vadose zone, temporally saturated soil zone, capillary fringe associated with groundwater table, wetlands, and subaqueous soils (soils formed in sediment found in shallow permanently flooded environments such as in an estuary; Demas and Rabenhorst, 2001). Three related key aspects are as follows:

- Hydrology has the potential to be an integrating factor for quantifying soil formation and evolution and for understanding soil changes upon global climate and land use changes (Lin et al., 2005). Hence, a focus on water can provide a potentially powerful means of quantifying and predicting dynamic soil functions.
- New ways of characterizing and mapping soils could or should be linked to hydrology, such as wetland boundary delineations, riparian zones, and hydropedologic functional units that are considered as soil–landscape units with similar pedologic and hydrologic functions (Lin et al., 2008b).
- The interpretation and quantification of soils as historical records of environmental changes in the past could be significantly improved if hydrologic data are considered simultaneously. This has been demonstrated in some paleosols and paleohydrology studies (Ashley and Driese, 2000).

35.3 Fundamental Scientific Issues of Hydropedology

At this stage of its development, the fundamental issues of hydropedology may be considered under the following four headings (Lin et al., 2005; Lin, 2010):

1. *Soil structure and horizonation in relation to in situ water flow and chemical transport*: Hydropedology emphasizes quantitative soil architecture of field soils across scales and their links to preferential flow in different spatial and temporal dimensions (see Section 35.4.1).
2. *Soil morphology and pedogenesis in relation to soil hydrology and soil change*: Hydropedology utilizes quantitative soil hydromorphology as a signature of soil hydrology and also uses soils as valuable records of environmental change over time (see Section 35.5).
3. *Soil catena and distribution pattern in relation to water movement over the landscape*: Hydropedology focuses on quantitative relationships between field soils and their surrounding landscape and the impacts of such relationships on hydrologic (and related biogeochemical/ecological) processes (see Section 35.6).
4. *Soil functions and maps in relation to carriers of soil quality and soil–landscape heterogeneity*: Hydropedology promotes quantitative delineations of functional soil units in the landscape as well as precision soil–landscape mapping for diverse applications (see Section 35.9).

35.4 Applications of Hydropedology

35.4.1 Soil Architecture and Preferential Flow

The natural soil "architecture" is of essence in understanding soil physical, chemical, and biological processes as well as landscape and ecosystem dynamics. It has been suggested that most that can be learned from sieved and repacked soil samples

has already been done, so whatever we do with soil hydrology should be done on intact, undisturbed soils, and preferably in situ. A new era of soils research will have to rely on "structure-focused," passing the stage of "texture-focused," to achieve better ways of quantifying flow pathways, residence times, and spatiotemporal patterns of landscape water.

Soil architecture is used here broadly to mean the entirety of how the soil is structured, which encompasses at least three parts: (1) solid components, including soil matrix (represented by soil texture and soil microfabric) and soil aggregation (represented by the type, quantity, and size distribution of peds and aggregate stability); (2) pore space, including the size distribution, connectivity, tortuosity, density, and morphology of various pores; and (3) interfaces between solid components and the pore space, such as coatings on peds or pores, and the macropore–matrix, soil–root, microbe–aggregate, and horizons interfaces.

Since soil structure generally refers to a specific soil horizon, the broader term of soil architecture used here also encompasses the overall organization of a soil profile (e.g., horizonation), a soil's relationship with the landscape (e.g., catena), and the overall hierarchical levels of soil structural complexity (Lohse and Dietrich, 2005; Lin et al., 2005).

Soil horizonation or layering is ubiquitous in nature, so it must be adequately addressed when measuring, modeling, and interpreting hydrologic processes in watersheds. Various kinds and thicknesses of soil horizons and how they organize in soil profiles reflect longtime pedogenesis and the past and current landscape processes (Mausbach and Wilding, 1991). The fact that natural soils are layered has at least two significant implications for hydrology: (1) interface between soil layers of contrasting textures and/or structures would slow downward water movement, which often leads to some kind of preferential flow (e.g., fingering flow, macropore flow, or funnel flow); and (2) soil layering or discontinuity in soil hydraulic properties between layers would promote lateral flow or perched water table, especially in sloping landscapes with a water-restricting layer underneath.

A catena (also called toposequence) is a chain of related soil profiles along a hillslope, with about the same age, similar parent material, and similar climatic condition, but differs primarily in relief that leads to differences in drainage and soil thickness. Catenary soil development often occurs in response to the way water runs down the hillslope and recognizes the interrelationship between soil and geomorphic processes (Hall and Olson, 1991; Moore et al., 1993; Thompson et al., 1997; Lin et al., 2005). Catenae are often called hydrosequences of related soils, especially in depositional landscapes (Schoeneberger and Wysocki, 2005). Another important aspect of soil architecture along the hillslope is related to preferential flow network, which is further discussed later in this section.

While the importance of soil architecture across scales has long been recognized in soil science and hydrology, its quantification and incorporation into models have been notoriously lagged behind. This problem is due to many factors, including (1) inconsistent and fragmented concepts of soil structure;

(2) overemphasis on ground-sieved soil materials and soil texture in the past, thus ignoring or downplaying the importance of the soil's "natural architecture." That natural soils are structured to various degrees at different scales is the rule, whereas the existence of a macroscopic homogeneity is the exception (Vogel and Roth, 2003); (3) lack of a comprehensive theory of soil structure/architecture formation, evolution, quantification, and modeling that can bridge orders of magnitude in scale and integrate physical, chemical, biological, and anthropogenic impacts. Although a hierarchical organization of soil aggregates has been well recognized (Tisdall and Oades, 1982; Vogel and Roth, 2003) and fractal characterization of soil structure has been proposed (Bartoli et al., 1998; Perrier et al., 1999), there is still a lack of means of representing field soil structure at different scales in a manner that can be coupled into models of flow, transport, and rate processes (Lin, 2003; Lin et al., 2005); and (4) lack of appropriate techniques and devices to quantify soil architecture directly, especially in situ noninvasively. Traditionally, soil structure has been evaluated by pedologists in the field using morphological descriptions or thin section observations, while soil physicists have employed wet and dry sieving, elutriation, and sedimentation to conduct aggregate analysis. In the absence of direct quantification, soil structure has been frequently evaluated by methods that correlate it to the properties or processes of interest (such as water retention, saturated hydraulic conductivity, infiltration rate, and gas diffusion rate). In recent years, noninvasive methods that permit soils to be investigated without undue disturbance of their natural architecture have become increasingly attractive, allowing 3D visualization of internal soil structure and its interactions with water. These methods include x-ray computing tomography, soft x-ray, nuclear magnetic resonance, gamma-ray tomography, ground-penetrating radar, and other methods (e.g., Anderson and Hopmans, 1994; Perret et al., 1999; Luo et al., 2008). Image analysis has brought new opportunities for analyzing soil structure, especially that of pores, their sizes, shapes, connectivity, and tortuosity (Vogel et al., 2002; Vervoort and Cattle, 2003). However, although numerous attempts have been made to find either statistical relations or deterministic links between soil structural data and hydraulic properties, a significant gap remains between in situ soil structure/architecture and field-measured soil hydraulic properties at different scales.

Quantifying soil architecture in the field across scales and at desirable spatial and temporal resolutions has been technologically limited (Tillotson and Nielsen, 1984). While landforms (e.g., digital elevation models or DEMs) and vegetation (e.g., land use/land cover) can now be mapped with high resolution (e.g., using LiDAR and IKONOS, respectively), there is a "bottleneck" phenomenon for in situ high resolution (e.g., submeter to cm) and spatially temporally continuous and noninvasive mapping or imaging of subsurface architecture including flow networks. This "technological bottleneck" has constrained our predictive capacity of many soil and hydrologic functions.

There is also a *conceptual bottleneck* that needs to be resolved for developing a new generation of hydrologic models. That is, should a continuous field or discrete objects be used to model surface and subsurface flow? Traditionally, hydrologic processes are generally conceptualized within the field domain (e.g., the Navier–Stokes equation and the Darcy's law) (Goodchild, 2007). Classical hydrology has applied findings from fluid mechanics, together with the necessary constitutive relations to develop sets of governing equations (much the same as atmospheric and ocean sciences have done). However, heterogeneities in land surface, hierarchical structures of soils, channel geometries, and preferential flow networks all make the land surface and subsurface different from the continuous field assumption (Kung, 1990; Noguchi et al., 1999) (CUAHSI, 2007; Lin, 2010). It is becoming more and more recognized that solid earth is not a continuous fluid; rather, it poses hierarchical heterogeneities with discrete flow networks embedded in both the surface and the subsurface. As McDonnell et al. (2007), Kirchner (2006), Beven (2002), and many others have noted, current models in watershed hydrology are based on well-known small-scale physics or theories such as the Darcy's law and the Richards equation built into coupled mass balance equations. It has been observed that the dominant process governing unsaturated flow in soils may change from matrix flow to preferential flow under different conditions when moving from the pore scale to the pedon scale (Blöschl and Sivapalan, 1995; Hendrickx and Flury, 2001). When moving from the pedon scale to the landscape/watershed scale, our knowledge for extrapolating the Darcy–Buckingham's law and the Richards equation to large heterogeneous area is further constrained (Weiler and Naef, 2003).

Because of heterogeneous soil architecture, variability in energy and mass inputs to soils (Addiscott, 1995; Warrick, 1998) diversity in biological activities, and nonlinear dynamics of hydrologic processes, preferential flow can occur in practically all natural soils and landscapes (Lin, 2010). As Clothier et al. (2008) summarized, preferential flow can occur spatially at the pore scale of spatial order 10^{-3} m, at the core scale (10^{-1} m), in pedons (10^0 m), down hillslopes (10^1–10^3 m) (Lehmann et al., 2007), through catchments (10^4–10^5 m), and across large regions of ≥10^6 m. Time-wise, preferential flow can operate during fluid flows at the temporal order of 10^0–10^1 s, during hydrological events 10^0–10^2 h, throughout seasonal changes 10^0 year, and across interannual variations of 10^1 years.

Based on three theoretical considerations and numerous published evidence, Lin (2010) has attempted to justify the likely universality of preferential flow in natural soils, inferring that the potential for preferential flow occurrence is everywhere in nature, although the actual occurrence of preferential flow depends on local conditions (Lin and Zhou, 2008). Lin (2010) also showed that networks are abundant in soils, such as root branching networks, mycorrhizal mycelial networks, animal borrowing networks, crack and fissure networks, artificial subsurface drainage networks, and pore networks between soil particles and aggregates. These networks provide preferential flow conduits, which in return reinforces or modifies the existing networks.

35.5 Soil Hydromorphology and Quantification

35.5.1 Water Tables and Inferred Soil Hydrology

Much of the research conducted in hydromorphology has focused on identifying the depth and duration of water tables to understand soil hydrology and the effects on pedogenesis and land use. Water tables are described as the top of the zone of saturation where water fills all or most of the pores in the soil to create saturated or satiated conditions (Daniels and Buol, 1992). The knowledge of soil hydrology has many practical applications for engineering, plant growth, reclamation, and remediation. The presence of free water in soils influences many related properties such as oxygen concentration (decreased aerobic respiration), reduction and transformation of redox couples (i.e., denitrification, metal reduction, and carbon dioxide production), change in solubility of compounds (bioremediation), change in soil pH, and decreased soil strength. Soils with high water tables generally lead to some challenges for land use such as decreased landscape stability (landslides), poor trafficability, limitations for onsite wastewater disposal, increased compaction, and poor fertility status (denitrification) in agriculture fields (Veneman et al., 1998). However, in more recent years, the benefits of wetlands and hydric soils have been recognized for their contribution to renovating contaminated waters and providing a source for groundwater recharge (Rabenhorst et al., 1998). Horizons are considered saturated when the soil–water pressure is zero or positive (Soil Survey Staff, 1999). The depth of the water table is related to multiple factors: (1) landscape position; (2) precipitation; (3) evapotranspiration; and (4) permeability of the surface and subsurface (Vepraskas, 1995). Understanding and interpreting the presence of water tables from landscape and soils information is important for understanding pedogenesis and land use. Soil morphology and redoximorphic features (formerly known as mottles) are used to imply the presence of water tables and inferred oxic–anoxic conditions.

### 35.5.2 Process of Redoximorphic Feature Formation

The presence of a water table results in a distinct morphology within a pedon and is the result of reduction–oxidation processes. The redox process results in the redistribution of primarily iron in natural soils, causing the soil to appear mottled. Although manganese is sometimes present and is an indication of alternating redox conditions, manganese is not as ubiquitous as iron. Additionally, the relationship between water tables and manganese is not as well correlated to water table durations and periodicity (Khan and Fenton, 1996; Fielder and Sommer, 2004). The iron segregations in areas within a soil are recorded as iron depletions and concentrations (Vepraskas, 1995; Vepraskas and Faulkner, 2001). The processes of reduction is driven by microorganisms; therefore, the soil conditions required to cause reduction

are heterotrophic facultative aerobic and anaerobic microorganisms, carbon source, saturated conditions (to decrease diffusion of O_2), and a temperature above biologic zero.

Microorganisms use carbon sources to obtain energy for life. For a simplistic example, Equation 35.1 represents the use of glucose and Equation 35.2 represents oxygen as final electron acceptor (Ponnamperuma, 1972).

$$C_6H_{12}O_6 \text{ ------->} 2CH_3\text{--}CO\text{--}COO^- + 6H^+ + 4e^-$$
$$\longmapsto \quad ATP \tag{35.1}$$
In aerobic soils, O_2 acts as the final electron acceptor as in Equation 35.2.

$$1.5O_2 + 6H^+ + 4e^- \rightarrow 2H_2O \tag{35.2}$$
As soils become saturated, the microorganisms continue to use oxygen until it is depleted. Once the oxygen is depleted, there are several other molecules that act as a final electron acceptor for the microorganisms. They are NO_3^-, Mn oxides, Fe oxides, sulfates, and CO_2. Given the temperature is above biologic zero, saturated conditions and a carbon source, the microorganisms through the production of electrons decrease the Eh, which creates conditions where reduced phase of the aforementioned compounds is thermodynamically stable.

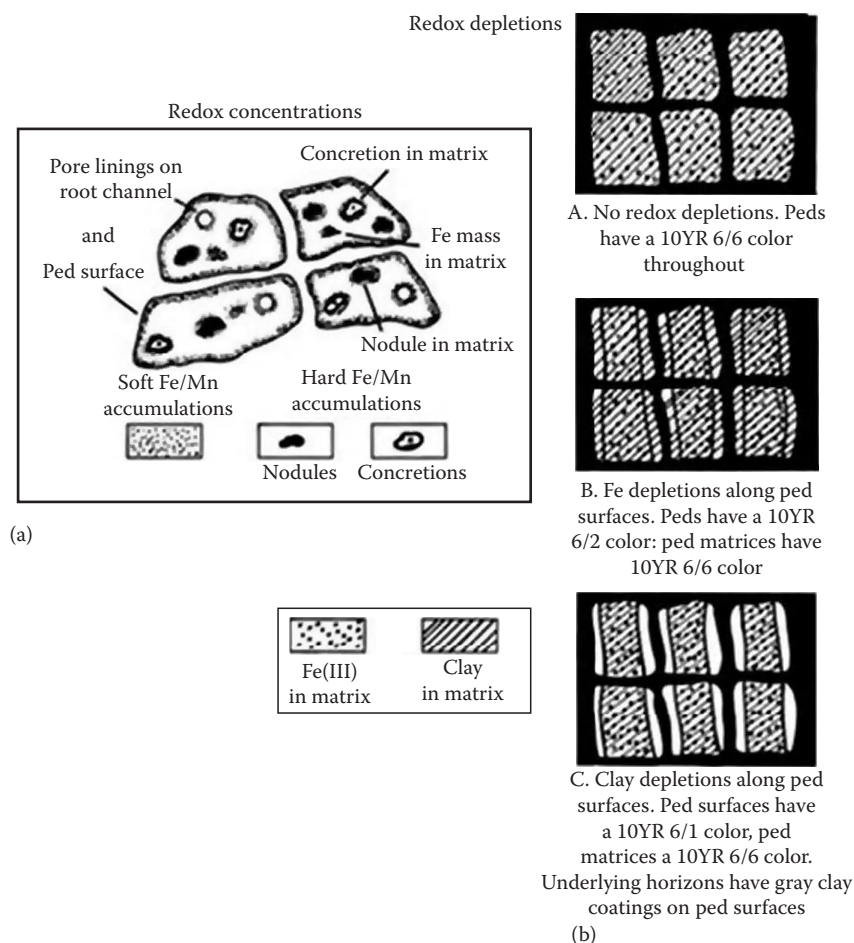
The difference in solubility of iron and manganese provides the mechanisms for redistribution and formation of redoximorphic features. Iron is stable and insoluble in aerobic environments as Fe^{3+} valence state. Once iron is reduced from Fe^{3+} to Fe^{2+}, it is soluble and mobile and can be redistributed in the soil matrix. The solubility product constant for $Fe(OH)_3$ is 6.3 × 10^{-38}, whereas for $Fe(OH)_2$, it is 7.9 × 10^{-15} (Kotz et al., 1994). The reduced ferrous iron will remain as Fe^{2+} until it encounters enough higher redox potential O_2 to oxidize, commonly when the water table begins to drop allowing O_2 to enter the system and increase the Eh. The formation of iron oxide minerals often occurs in pore channels, on structure surfaces, and within the soil matrix (Vepraskas, 1995; Figure 35.3). Soils with a dominant gray matrix color are depleted of iron and display the color of minerals with minimal or no iron oxide coatings.


FIGURE 35.3 Schematic illustration showing different kinds of redox concentrations and their relationship to soil macropores and matrices (a). Schematic illustrations of redox depletions showing changes in color and texture as ped surfaces develop Fe depletions and clay depletions (b). (From Vepraskas, M.J. 1995. Redoximorphic features for identifying aquic conditions. Technical Bulletin No. 301. North Carolina State University, Raleigh, NC.)

35.5.3 Relationship of Redoximorphic Features and Soil Hydrology

Data on soil morphology and soil–water relationships are important because collecting water table information with wells and peizometers is time-consuming and expensive. There have been many studies relating soil morphology to the presence or absence of free water in soils (Daniels et al., 1971; Simonson and Boersma, 1972; Veneman et al., 1976; Franzmeier et al., 1983; Vepraskas and Wilding, 1983a, 1983b; Zobeck and Richie, 1984; Griffin et al., 1992; Jenkinson and Franzmeier, 2002). Researchers have focused on correlations between water table levels and morphological soil characteristics. One of the diagnostic redox features commonly used to define limitations due to the duration of water tables is the depth to chroma ≤2 depletions. Depth to gray mottles has been characterized extensively in many soils (Latshaw and Thompson, 1968; Simonson and Boersma, 1972). Yakovleva (1980) found a good general relation between depth to water table and degree of gleying in soils, and Daniels et al. (1971) found that the gray mottles were associated with different degrees of saturation in different landscape positions. More recent investigations by Evans and Franzmeier (1988) and Jenkinson et al. (2002) in Indiana and Megonigal et al. (1993) in South Carolina correlated length of soil saturation with color in alfisol soil toposequences derived from glacial till and a floodplain-terrace soil toposequence developed from tertiary bedrock, respectively. Thompson and Bell (1996) in Minnesota, observed a relationship between the surface accumulation of organic matter in mollisols and duration of saturation. Several researchers (Veneman et al., 1976; Vepraskas and Bouma, 1976; Richardson and Lietzke, 1983) have found that, in general, very brief periods of saturation are associated with high chroma peds with manganese and iron concentrations. Intermittent periods of saturation are associated with bright Fe concentrations, ped ferrans, and some Mn cutans. Saturation persisting for several months in a year is associated with <2 chroma matrix interiors, ped surface depletions, pore and root channel depletions, and virtually no Mn cutans or nodules. Since soil color patterns are strongly influenced by the chemistry and mineralogy of iron and manganese compounds, their solubility status determines the color of the soil matrix and argillans and determines the type and distribution of iron concentrations in a horizon.

Quantification of the time of saturation related to redox features has been reported in a few studies. In Indiana, Franzmeier et al. (1983) found the following soil morphology–soil–water relationships: (1) gleyed horizons with dominant colors of chroma ≤2 are saturated most of the year, (2) horizons with a dominantly brown matrix with gray depletions are saturated a few months of the year, and (3) horizons with a chroma of 5–6 that lack depletions ≤3 are seldom saturated during the growing season unless they were near a gleyed horizon. In study within the coastal plains of Georgia, Jacobs et al. (2002) found that soil horizons with chroma <2 were saturated >50% of the time. Horizons with low chroma iron depletions can be saturated as little as 18% of the time. In three representative floodplains in Maryland

and Delaware, Vaughan et al. (2009) found that with lower temperatures, longer durations of saturation were needed for iron reduction with respect to ferrihydrite (FH). For temperatures greater than 90°C, less than 2 days were required for iron reduction with respect to FH; and as many as 20 days for iron reduction with soil temperatures between 1°C and 3.9°C (Vaughan et al., 2009).

However, these observations and measurements have been mostly limited to a point pedon scale and other research has shown that there are various degrees of expressions of redoximorphic features described that relate to movement and residency of water as controlled by landscape (Richardson et al., 1992; Jenkinson, 1998).

35.5.4 Soil Hydrology within Landscapes

Landscape hydrology has been the focus of research since the 1960s culminating with an intensive group of studies titled the Wet Soil Monitoring Project (WSMP). The WSMP was funded and coordinated by USDA–NRCS between 1990 and 2001. The studies were national in scope and included most climatic temperature and moisture regimes. This group of studies found that the geomorphic surface and the stratigraphy of soil horizons control water table depths in the soil, the amount of time the soil stays saturated, and the direction (vertical and or horizontal) water flows into or across the landscape. In turn, landscape hydrology governs the range of soil moisture regimes, oxidation–reduction processes, and soil color patterns (Arndt and Richardson, 1988; Griffin et al., 1992; Richardson et al., 1992; Hopkins, 1996; Thompson and Bell, 1996; Jenkinson, 1998, 2002; Feigum, 2000; Owens, 2001).

The presence and movement of groundwater through the landscape influences many of the physical and chemical processes that are involved in soil development. The water table, duration of saturation, and the flow of water across and through the landscape are controlled by topography and stratigraphy (Jenkinson, 1998). Richardson and Daniels (1992) concluded that changes in topography exert a strong influence on groundwater flowing through a landscape, and that landscapes can be subdivided into a system of groundwater recharge, flowthrough, and discharge that, under stable long-term conditions, can transfer soluble materials through the groundwater system in distances measured in kilometers. Richardson and Daniels (1992) observed these effects on landscapes in North Dakota and in the southeastern region of the United States. Thompson and Bell (1996) related the hydrological profile of soils along a toposequence in Minnesota to the geomorphology of the landscape. Daniels et al. (1971), in characterizing North Carolina landscapes, found a statistical correlation between water table depth and closeness to the dissected edge. These data indicated that shoulder positions within landforms are well drained due to lateral water movement and decreased residency time.

Additionally, the knowledge accumulated by the WSMP studies created a platform for the interpretation of hydrosequences, especially of soil drainage conditions, that are critically important when making land use decisions. The WSMP studies, gave

researchers insights into what types of instrumentation worked well and what measurement processes could benefit from new technologies. Traditionally, water tables and anaerobic conditions induced by poor drainage conditions have been evaluated by wells, peizometers, tensiometers, open boreholes, alpha, alpha-dipyridyl, and platinum electrodes for Eh measurement. However, the Eh values obtained from platinum electrodes were generally considered circumstantial and occasionally suspect (Owens et al., 2008; Rabenhorst et al., 2009). Recent research by Rabenhorst et al. (2009) indicated that more accurate Eh values can be determined by using voltmeters with high input resistance (20 GΩ) and data loggers with standard configuration that maintains an open circuit during the instantaneous measurement. The need for a new method to address the issue of saturation and anaerobiosis together led to the development of a new device called indicator of reduction in soils (IRIS). IRIS was developed at Purdue University (Jenkinson, 2002) at the end of the WSMP period and further refined by Rabenhorst et al. (2008). IRIS mimics natural soil processes, visually indicates soil reduction, that can be quantified and be robust (Castenson and Rabenhorst, 2006). IRIS is a PVC tube coated with colored Fe minerals, mostly FH, that dissolves under reducing conditions (Jenkinson and Franzmeier, 2006). In practice, IRIS tubes are inserted into a soil, removed after a few weeks or longer, and evaluated by visually inspecting the coating in the field. If the coating was not dissolved, no reduction occurred, but if it was dissolved, reducing conditions must have prevailed (Figure 35.4). Another field technique using zero valent iron rods was developed to infer O_2 concentration (Owens et al., 2008). Iron rods were polished and placed in toposequences and compared with O_2 measurements, piezometer data, and Eh measurements. The coatings on iron metal rods correlated well with specific oxygen ranges. Rods in soils with O_2 concentrations below

about 3 mg L^{-1} did not develop bright (7.5YR 4/4–5/8) oxide/oxyhydroxide coatings but instead formed black (10YR 2/1–2/2) coatings. Rods in soils with O_2 concentrations between about 2% and 5% developed variegated bright (7.5YR 4/4–5/8) oxide/oxyhydroxide coatings indicating microsite differences in O_2 concentrations. Rods in soils with O_2 concentrations above about 5% with adequate moisture were almost completely coated with bright (7.5YR 4/4–58) iron oxide/oxyhydroxides. This method provides a simple and inexpensive means to qualitatively estimate the ranges of O_2 status in soils.

Many soil hydrology studies were conducted at the pedon scale and along catenae. In these studies, soil–water tables were highly correlated to landscape position or topography of the landscape. The term hydrosequence is used to a series of soils with different degrees of wetness due to topography (Schoeneberger and Wysocki, 2005). Soil moisture regime and presence of water tables can be attributed to several factors; however, precipitation and topography are the two most dominant factors at field scale. Other important factors contributing to water table dynamics are the underlying stratigraphy and particle size of the parent material. Water may flow through hydraulically conductive upper horizons and "perch" on horizons with low hydraulic conductivity. In sandy parent materials with high hydraulic conductivity, the presence of a water table may not be evident.

Studies have indicated that within similar climate conditions, topography and parent material stratigraphy are the two most important controlling factors of water tables. In central Iowa, Khan and Fenton (1994) found that within an internally drained glacial till landscape, soils in depressions had longer duration of water tables with higher organic carbon when compared to higher topographic soils. Soils in the depressions also had different chemical properties. In the wettest part on the landscape, Bkg horizons formed where calcareous water was discharged. Similarly Richardson et al. (1992) found that flownet analysis based on stratigraphy and water table position was useful for describing observed differences in soils related to recharge and discharge positions in the landscape. Considering the soils in the context of the landscape, Richardson et al. (1992) identified four kinds of water movement that dominate soil development: (1) recharge or dominantly downward flow of water; (2) flowthrough or lateral groundwater movement; (3) discharge or movement from the water table either to or near the soil surface; and (4) stagnation or slow water movement creating water table mounds. This analysis indicated that leached soils and absence of carbonates were found in the recharge soils. Soils within discharge zones and flowthrough positions had accumulations of carbonates and gypsum reflecting the addition of carbonate-rich water at lower landscape positions from higher landscape positions (Figure 35.5). Rolling topography with steep hillslopes commonly have complex shallow hydrologic system where water moves laterally above a limiting layer (Daniels and Buol, 1992). Evans and Franzmeier (1988) found water flowing laterally on hillslopes remained oxygenated and did not lead to reducing conditions. Therefore, the interpretations of redoximorphic features must be placed in the context of landscapes.

FIGURE 35.4 Photos of IRIS illustrating the degree of iron reduction on the rods. The degree of reduction and stripping of iron relates to the intensity and duration of saturated conditions in the soil.
FIGURE 35.5 An examination of soils from (a) Iowa, (b) North Dakota, and (c) Saskatchewan found that the soils in the depressions varied such that the soils from Iowa indicated discharge, North Dakota had recharge in the higher areas and flowthrough and discharge in the lower areas. The Saskatchewan had a dominance of recharge wetlands with argillic horizons. (From Richardson, J.L., L.P. Wilding, and R.B. Daniels. 1992. Recharge and discharge of groundwater in aquic conditions illustrated with flownet analysis. Geoderma 53:65–78.)

Utilizing hydropedology concepts in soil morphologic studies is promising because soil properties that influence water distribution can be better understood and water–soil morphology relationships can be placed in the landscape context. The availability of digital information coupled with the ability to display spatial information will provide the potential to make significant advances for quantifying the spatial–temporal relationship between soil morphology and soil hydrology within larger landscapes. This will be discussed further in Section 35.9.

35.6 Coupling Hydropedology and Biogeochemistry

A biogeochemical cycle is a pathway by which a chemical element moves through biotic (biosphere) and abiotic (lithosphere, pedosphere, atmosphere, and hydrosphere) compartments of the earth system. Biogeochemical cycles are inseparable from the hydrologic cycle (NRC, 1991), and fluxes of elements and rates of biogeochemical cycling are often linked to hydrologic conditions (Richardson et al., 2001). Zones of enhanced fluxes and reaction rates where terrestrial and aquatic ecosystems meet have been recognized, or suspected, for decades (Lohse et al., 2009). *Biogeochemical hot spots* are patches in the landscape that show disproportionately high reaction rates relative to the surrounding matrix, whereas *hot moments* are defined as short periods of time that exhibit disproportionately high reaction rates relative

to longer intervening time periods (McClain et al., 2003). Hot spot and hot moment activity is often enhanced at terrestrial–aquatic interfaces. For example, using examples from the carbon and nitrogen cycles, McClain et al. (2003) showed that hot spots occur where hydrological flow paths converge with substrates or other flow paths containing complementary or missing reactants. Hot moments occur when episodic hydrological flow paths reactivate and/or mobilize accumulated reactants.

Since hydrology often triggers hot spots and hot moments of biogeochemical reactions and ecological functions (Bundt et al., 2001; McClain et al., 2003), improved modeling and prediction of soil architecture and preferential flow will have considerable implications for determining chemical fluxes and calculating elemental budgets in soils and ecosystems. Interpretation of point measurements without knowing preferential flow paths is now often questioned (Gottlein and Manderscheid, 1998; Netto et al., 1999), because the uncertainty of whether soil solution is extracted from stagnant or high velocity flow paths makes it practically impossible to reliably determine mass flux rates. Additional complications arise in structured soils for reactive components due to locally variable chemical conditions. In addition, macropore linings and aggregate coatings restrict lateral mass transfer and reduce sorption and retardation; hence, physical and biochemical nonequilibriums are enhanced. All these suggest the need to identify and model preferential flow pathways and networks in real-world soils if we are to improve the modeling and prediction of interactive soil physical, chemical, and biological processes.

At the pedon scale, soil aggregation, macropore networks, horizonation, and the soil–bedrock interface have important impacts on preferential flow and biogeochemical reactions in soil profiles (Deurer et al., 2003; Field et al., 1984; Flury et al., 1994). At ped surfaces, for example, C and N contents and microbial activities are higher than in those in ped interiors (Tisdall, 1995; Alef and Kleiner, 1989; Kavdir and Smucker, 2005). Soil layering can trigger on or off preferential flow between soil horizons with different textures and structures, which tend to promote lateral flow in sloping landscapes. The soil–bedrock interface has also been recognized as important subsurface preferential flow pathway (Li et al., 1997; Freer et al., 1997; McGlynn et al., 2002). Flühler et al. (1996) have suggested three regimes of flow and transport within a soil profile during a preferential flow process: (1) lateral distribution flow in the *attractor zone* where preferential flow is initiated; (2) downward preferential flow in the *transmission zone* where water moves along preferential flow pathways and bypasses a considerable portion of the soil matrix (Quisenberry et al., 1993; Vervoort et al., 1999); and (3) lateral and downward dispersive flow in the *dispersion zone* where preferential flow pathways are interrupted and water flow becomes more or less uniform again.

Based on a review of studies documenting soil microbial biomass distributions with depth (Balkwill and Ghiorse, 1985; van Gestel et al., 1992; Dodds et al., 1996; Murphy et al., 1997; Richter and Markewitz, 2001; Blume et al., 2002; Taylor et al., 2002; Fierer et al., 2003), the system of Flühler et al. (1996) can be applied. Various studies have demonstrated a consistent pattern of changing microbial biomass size and activity distribution,

characterized by three broad zones with distinct biogeochemical potentials that correspond to the three flow zones of Flühler et al. (1996): (1) *attractor zone*, equivalent to the A horizon and representing high-biomass surface soils under the strong influence of plant roots, moisture, and temperature; (2) *transmission zone*, equivalent to B and C horizons and representing lower more spatially heterogeneous biomass than in the *attractor zone* (Konopka and Turco, 1991; Rodríguez-Cruz et al., 2006); and (3) *dispersion zone*, representing higher-biomass, water-capture zones at the soil–bedrock interface or right above a water-restricted soil layer because of moister and more nutrient-rich conditions resulting from impeded or lateral flow (Dupuy and Dreyfus, 1992; Buss et al., 2006). These three zones are distinguished from "deep-subsurface" aquifers and geologic materials, many of which have extremely low biomass (Balkwill et al., 1985; Kieft et al., 1995). Contributions of greenhouse gas fluxes from the *attractor zone* have been studied intensively (Konopka and Turco, 1991; Krasovskaia et al., 2003; Rodríguez-Cruz et al., 2006), whereas contributions from the *transmission and dispersion zones* are essentially uncharacterized and will likely depend on their connectivity to the atmosphere or on preferential gas flux associated with preferential water distribution.

35.7 Scale Dependency of Soils and Modeling

As previously discussed, a lot of work has been conducted on measuring and understanding of preferential flow at point pedon scale and its role on soil development and hydrological process at landscape scale; however, a much broader context especially in terms of varying scales is needed. The spatial and temporal scales have been long recognized by soil science (Jenny, 1941; Soil Survey Division Staff, 1993; Wilding, 2000; Soil Survey Staff, 2003; Sposito, 1998; Tugel et al., 2005). Different schemes of soil classifications have captured soil variability at different scales from field to hillslope, landscape, watershed all the way to regional continental and world scales (Soil Survey Division Staff, 1993; Boul et al., 2003; Soil Survey Staff, 2004). Various criteria and principles have been used to classify soils and their properties across various scales represented by different modes such as state factor model (Jenny, 1941), process model (Simonson, 1959), energy model (Runge, 1973), statistical landscape models (Shovic and Montagne, 1985; Bell, 1990; Zhu et al., 1996, 1997, 2001, 2006; Havens, 1998; Zhu, 2000), and geostatistical models (Odeh et al., 1992, 1994; McBratney et al., 2003). The evolution of soil models along with that of tools and purposes of soil mapping have highlighted some of the issues related to the current soil maps and soil survey in general. The issues identified encompass a wide range related to the type and level of soil information provided and current delivery format of soil data (McBratney et al., 2003; USDA–NRCS–NGDC, 2006; Hempel et al., 2008; MacMillan, 2008).

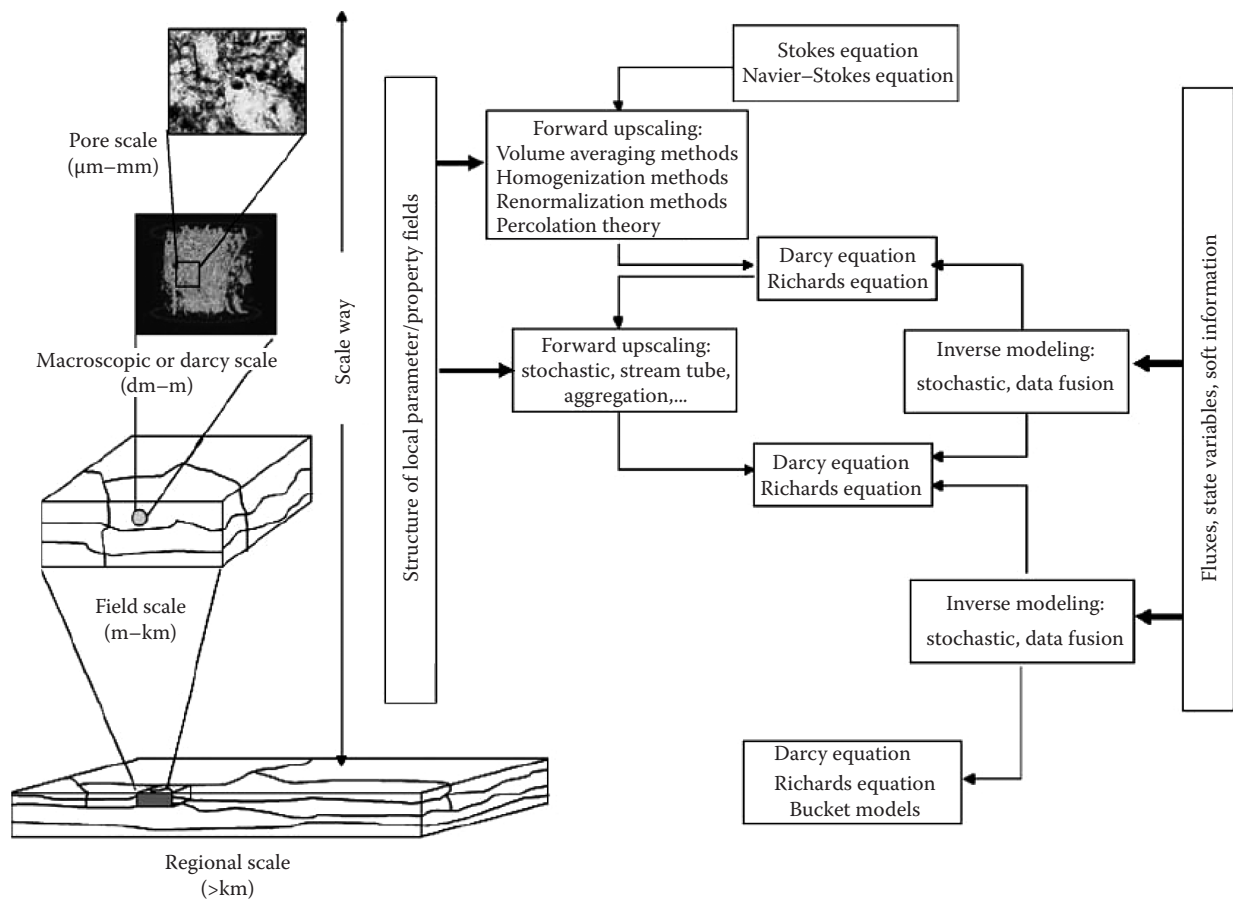
The majority of the soil information comes from field descriptions of pedons and laboratory measurements of soil samples collected from these pedons and it is of three types: (1) quantitative, (2) qualitative, and (3) semiqualitative/quantitative. The field descriptions include qualitative statements about soil horizons, soil structure, consistency, color, and texture; quantitative statements about soil horizon thickness, redoximorphic features, degree of mottling, and nutrients; and semiqualitative statements about roots and pores among others (Schoeneberger et al., 2002). The need to use this information in hydrologic modeling has led to the development of PTFs as a way to translate qualitative and semiqualitative soil information to quantitative one (Bouma, 1989; Pachepsky et al., 1999; McBratney et al., 2002; Pachepsky and Rawls, 2003, 2004; Wagenet et al., 1991). The value of PTFs has been widely recognized because of their multiple applications in estimating and predicting soil hydraulic properties (McBratney et al., 2000; Lin et al., 2005; Pachepsky et al., 2006) and also for their use in modeling in general (McBratney et al., 2002). McBratney et al. (2002) points out that PTFs are typically limited to specific geomorphic regions or soil types and lack quantifiable uncertainty. Such efforts have led to the emerging of hydropedology as a promise to bridging pedology and hydrology (Lin et al., 2005; Bouma, 2006; Pachepsky et al., 2006, 2008). These advancements have highlighted one of the major challenges related to the use of PTF and hydropedology, that is, the transferability of the qualitative, quantitative, and semiqualitative/quantitative field measured and estimated soil information across multiple scales (Bouma, 2006). In his discussion about different conceptual frameworks and methods that have been developed to address this issue, Bouma (2006) challenges the soil scientists for the fact that soil expertise is not adequately represented in modeling. Bouma (2006) recognizes the fact that pedologists in general are not comfortable with representation of soils in terms of homogeneity and isotropy needed by hydrologists for modeling purposes. Evidence shows that certain measured hydraulic soil properties display both stochastic and deterministic behavior (Harlan and Franzmeier, 1974; King and Franzmeier, 1981; Evans and Franzmeier, 1986; Franzmeier, 1991; Haws et al., 2004; Zeleke and Cheng Si, 2005; Botros et al., 2009). Franzmeier (1991) measured K_{sat} on different soils across Indiana and found similar values by grouping soils based on the parent materials, soil horizon, and soil texture categories indicating the presence of stochastic behavior of K_{sat} within each category and deterministic behavior across categories. Haws et al. (2004) used the representative measurement area (RMA) concept to describe the behavior of measured K_{sat} and found that an RMA greater than $400 \, cm^2$ was needed to filter out smaller-scale heterogeneities and a distance between 120 and 200 m to capture the effective or deterministic behavior of K_{sat} at landscape scale. The conclusion of the study was that in modeling water flow into and through soils, the measured K_{sat} should integrate across the range of variability at the scale of interest. Iqbal et al. (2005) using geostatistical analysis (kriging and structured variograms) of soil physical properties like soil bulk density (ρb), saturated hydraulic conductivity (K_s), and soil–water content (θ) showed that soil texture displayed spatial structure or


FIGURE 35.6 Forward and inverse upscaling methods to upscale soil–water flow processes from the local to the field scale. (From Vereecken et al., 2007.)

autocorrelation within a 400 m distance while hydraulic properties and bulk density within a 100 m distance beyond which the distribution of measured values displayed random behavior. Similar results have been found by other researchers (Ersahin, 2003; Kozak and Ahuja, 2005; Vereecken et al., 2007) for soil infiltration rates and other soil properties (Iqbal et al., 2005). Vereecken et al. (2007) discusses the "scaleway" approach first introduced by Vogel and Roth (2003) in upscaling soil hydraulic properties across multiple scales (Figure 35.6) and provides a summary of the upscaling methods.

Methods like fractals have also been proposed for upscaling soil hydraulic properties (Shepard, 1993; Peyton et al., 1994; Baveye and Boast, 1999; Rodriguez-Iturbe and Rinaldo, 1997; Perret et al., 2003) along with other approaches. The method is based on the concept of self-similarity of geometrical shapes displayed by disordered systems that appear similar over a range of length scales. Such structures are self-similar and are referred to as geometrical fractals (Perret et al., 2003). The characteristic of a geometrical fractal is its fractal dimension, D, which can be 1, 2, and 3 for 1D, 2D, and 3D geometric shapes. The dimensions can be determined by measuring the length, area, or volume depending on the geometric shape. The method has been used to quantify pore volumes and pore tortuous paths and relate them to soil hydraulic conductivity (Shepard, 1993). The fractal

methodology approach can also be useful for understanding and upscaling soil properties using pattern recognition.

The majority of the discussions about soil spatial variability has been focused on soil properties especially hydraulic properties (Grayson and Bloschl, 2000; Ersahin, 2003; Kozak and Ahuja, 2005; Corwin et al., 2006; Vereecken et al., 2007). However, the majority of soil properties are represented spatially by soil series and soil map units. In this context, two levels of information could be distinguished to characterize the representation of spatial distribution of soil property data, that is, within and between soil map units. Research conducted on deriving certain soil hydraulic properties from soil series and soil map units (Ersahin, 2003; Kozak and Ahuja, 2005) has highlighted some issues related to the spatial representation of these properties. The majority of soil property data has been measured or estimated at point or pedon scale and transferred to polypedon, soil series, and soil map unit scales (Soil Survey Division Staff, 1993). The spatial distribution of these transferred properties comes in the form of representative values (Soil Survey Staff, 2004) or mean values with ranges with no indication about their spatial distribution within soil map units (Libohova et al., 2010). Furthermore, often ranges between soil series and soil map units overlap rendering them not statistically significant. In addition, soil map units are not always pure with only one representative

soil as they could be complexes and/or associations with smaller inclusions of other soil types (Soil Survey Division Staff, 1993). Taxonomy and management related interpretations have both played a role in the current design of soil map units. Least but not last, political boundaries and time differences between soil survey conductance has introduced further variability that may not necessarily reflect the reality. How much of this variability is real and how much is overrepresented and could be simplified is a question that relates directly to the representation of spatial variability of soil properties. Efforts to address these issues have led to the development of most recent concepts like "functional homogeneity" versus "structural heterogeneity" of soil series and soil map units for parsimonious watershed modeling and predictions (Basu et al., 2009). The presence of overlapping ranges of soil properties between soil map units constitutes at the same time recognition of their continuum spatial variability from the soil scientists and surveyors. It is a reflection of the purpose of soil surveys and the limitations of the tools used at the time of soil survey campaigns. Recent developments in spatial tools and technologies offer an opportunity to significantly improve the current delivery format of spatial soil information (McBratney et al., 2003). U.S. Soil Survey Program has adapted the major land resource area (MLRA) concept (Indorante et al., 1996) and started the so-called edge-matching in an effort to create seamless soil maps for the conterminous United States. European Union has launched similar efforts despite the surmountable obstacles due to differences in soil classification systems, time, and purpose of the soil survey conductance and resistance to share data deemed often a matter of national security for some countries (European Communities, 2007). The most recent global soil map initiative aimed at creating the first world digital soil map (McMillan, 2009) has taken these efforts to another level and created an opportunity for the soil surveys around the world to come together like never before.

A plethora of methods have been developed to aid the efforts for creating spatially continuous soil maps and especially soil property maps from the existing soil information. McBratney et al. (2003) provide an extensive review of methods developed for DSM by establishing quantitative relationships between soil properties or classes and their "environment" often referred to as DEM-derived terrain attributes. Some of the methods discussed include generalized linear models, classification and regression trees (CART), neural networks, fuzzy systems, and geostatistics (McBratney et al., 2003). These and other methods have been necessary to address the existence of different levels and types of soil information and in some cases the lack of soil information. The major drives for these developments have been the great progress in geographic information systems (GIS), GPS, remote sensing, and data sources.

DEMs coupled with increasing demands for soil data and information from environmental sciences and modeling (McBratney et al., 2003). Soil science is now faced with the challenge of looking beyond its own domain and sharing paths more than in the past with other disciplines such as ecology and hydrology, just to name few (Lin et al., 2005; Wilding and Lin,

2006). This may require soil scientists to become familiar with the concepts and terminology used by other disciplines in order to establish mutually beneficial communication. A closer look at hydrological and/or ecological sciences reveals similarities with soil science for engaging in modeling different aspects of natural process being soil, water, vegetation, and wildlife (Corwin and Wagenet, 1996; Laurenson, 1974; Ibanez et al., 1995; Sayfried and Wilcox, 1995; Phillips, 2001; Austin, 2002; Burke and Lauenroth, 2002; Epstein et al., 2002; Kie et al., 2002; Shirazi et al., 2003; Hopmans and Schoups, 2005; Lu et al., 2005; Sivapalan, 2005; Logsdon et al., 2007; McDonnell et al., 2007; Wagener et al., 2007; Simmons et al., 2008). A revisit of different concepts used by these disciplines in the light of spatial variability representation is very important as "a better understanding of spatial soil variability, its development over time (pedogenesis) and its functional relationships to recent processes in soil landscapes is one of the biggest challenges in soil science" (Sommer, 2006).

In soil science, the pedon definition and its spatial limits are used to separate soils within a small-scale pattern of local variability, usually $1-10 \, m^2$, while polypedon is presented as a unit of classification or a relatively homogenous soil body whose limits are extremely hard to find (Soil Survey Division Staff, 1993). Because of this difficulty, the polypedon concept has been ignored by most soil scientists due to its circulatory nature, and, thus, its properties and extent have been transferred to the pedon. The concept has been further expanded spatially by the use of soil series and soil map units that are viewed often as a collection of polypedons (Soil Survey Division Staff, 1993). The practical applications of these concepts have been difficult in representing the soil as true continuum. This has resulted in soils and soil map units with overlapping ranges for most of the soil properties (Lin et al., 2005), thus introducing more spatial variability than could be present. Using the analogy from Logsdon et al. (2007), the spatial variability within soil map units would be considered as random fluctuations or noise. However, the spatial variability between soil map units may or may not be random depending on the soil property and the predicted function (Libohova et al., 2010). The distinction between these two spatial variability categories is scale dependent (Logsdon et al., 2007). Hydrology and hydrologic modeling in particular utilizes similar concepts but uses terminology such as "deterministic length scale" (Sayfried and Wilcox, 1995), representative elementary area (REA) (Wood et al., 1988; Wood, 1999) closely related to the representative elementary volume (REV) (Peck, 1983), and RMA (Haws et al., 2004) used in soil science in order to emphasize scale dependence of variability. Other terms like "stochastic," "deterministic," "homogenous," and "heterogeneous" are used in the same manner in describing hydrologic processes; and the distinction among them is scale dependent (Haws et al., 2004). Sayfried and Wilcox (1995) acknowledge that spatial variability is "rarely entirely deterministic or stochastic" as noted also by other researchers (Laurenson, 1974; Vogel et al., 2000). Both trends are found in every hydrologic parameter, and the dominance of one or the other has been found to be scale dependent. In this context, the authors describe the definition of "deterministic length

scale," meaning that depending on the scale, spatial variability of any parameter can be characterized as deterministic, thus the variability can be represented by a single value or function rather than a range of values with some probability distribution as in the stochastic case. Ecological sciences use terms like "numerical richness" (Kempton, 1979) and "species density" (Hurlbert, 1971). Ibanez et al. (1995) relates these terms to the ratio of the number of different soil taxa over the total number of pedons described and the number of soil taxa per sampling area, respectively. Burke and Lauenroth (2002) discuss the challenges related to representation of the regional scale variability facing the ecological sciences especially the limitations of local-scale and short-term studies in capturing regional scales. The common feature of discussions about the spatial distribution of soils or soil properties, hydrological process, or ecological species diversity is the fact that they are all bound within a certain spatial domain and the nature of their variability is scale dependent. The focus so far has been on spatial variability, but the same can be stated for temporal variability (Tugel et al., 2005; Sommer, 2006; Logsdon et al., 2008) especially when considering the human impact as Basu et al. (2009) showed on the role of tile drains on controlling hydrologic response in the Midwest. The difference in scale representation of variability can be addressed, and soil structure and hydrologic functioning at different scales can be related within the same spatial units as pointed by Pachepsky et al. (2008).

The continuous soil maps and soil property maps most likely will be in a raster format; thus, the selection of the appropriate pixel resolution is also important. The selection of pixel size is also scale related and depends on the soils and soil properties to be inferred. Soil properties manifest varying degrees of spatial dependence (McBratney and Webster, 1983) as do the terrain attributes (Gessler et al., 1995), and they need to be taken into consideration; otherwise the derived terrain attributes may have no meaning and the soil pattern or process could be lost as Moore et al. (1991, 1994) have found. McBratney et al. (2000) provides a review of resolutions and scales used for soil survey and suggests pixel sizes of >2 km, 20 m^{-2} km, and <20 m for national to global, catchment to landscape, and local extents, respectively. In a more detailed overview, McBratney et al. (2003) provide pixel resolution based on the order and scale of the soil survey and identify the 5–20 m pixel resolution as the suggested one for U.S. soil survey order 1 and 2 corresponding to scales 1:5,000–1:20,000. Winzeler et al. (2008) found that a pixel size resolution between 5 and 10 m in relatively flat glaciated landscapes in Northern Indiana can capture the local relief and the spatial distribution of selected soil properties without losing valuable information on patterns and variability at the landscape scale, avoiding at the same time unnecessary microrelief details often described as "noise."

The challenge for soil science is not only to accurately and completely represent the spatial variability of soil properties but also to relate this variability to scales. For hydrologic purposes, this means that soil morphological differences need to be viewed also from the hydrologic processes perspective, thus leading to the generation of soil functional hydrologic property maps with a focus on commonality rather than morphological differences.

The approach parallels that of the catchment hydrology major challenge described by Sivapalan (2005) and McDonnell et al. (2007) as a shift from prescribing patterns of catchment heterogeneity to focusing on the search for (1) geomorphic or landform processes that generated these patterns; (2) processes that underlined this heterogeneity and complexity; and (3) the ecological, pedological, and geomorphological functions of these processes. Just as the focus on pattern, process, and function will revolutionize hydrology (Sivapalan, 2005), the same might be stated for soil science in general and soil modeling in particular. This means that mapping soils and soil map units, soil morphological and taxonomic differences as well as soil heterogeneity, need to be linked with scales, hydrological, and soil-forming processes in order to look at the soil map units from the functional in addition to compositional perspective. The variability is everywhere, and before any attempts to characterize it quantitatively, we should ask questions about "purpose" and "scale" or "boundary conditions" as there may not be a universal solution or a silver bullet to address all the variability due to the fact that the nature of variability (stochastic, deterministic, chaotic, or homogenous) is scale dependent as are the hydrological process in hydrology and other disciplines from ecology all the way to social sciences. Recent developments in DSM (McBratney et al., 2003), coupled with PTFs and the emergence of hydropedology (Pachepsky et al., 2006), provide a platform for addressing the scale dependency of soil variability related to modeling.

35.8 Pedotransfer Functions

"Data rich, information poor" (information here connotes interpretation, synthesis, and utilization of data) has been a common syndrome in many disciplines (Lin, 2003). This problem is largely due to data fragmentation, incompleteness, incompatibility, inaccessibility, or lack of interpretation and synthesis in spite of past extensive and costly data collections. In soil science and hydrology, it is recognized that gaps exist between what is available (e.g., the National Cooperative Soil Survey [NCSS] Program databases) and what is needed (e.g., soil hydraulic parameters and PTFs needed for simulation models). Improved procedures to extract useful information from the available databases and to improve and interpret soil survey data for flow and transport characteristics in different soils are needed.

With the increasing popularity of coupling GIS with vadose zone models and soil survey databases for diverse natural resource applications, the demand for soil hydraulic information has increased significantly in recent years. However, the lack of sufficient field data on soil hydraulic properties often limits the application of contaminant transport and hydrological modeling. Existing methods for direct field measurement of soil hydraulic properties remain complex, time-consuming, and costly (Mualem, 1986; Bouma, 1989), despite decades of work by soil physicists, hydrologists, and others representing different disciplines. Another limitation of direct field measurement is significant spatial and temporal variability, hence demanding a large number of measurements that are often prohibitive in terms of

time and money (van Genuchten et al., 1999b). This has prompted efforts to indirectly estimate soil hydraulic properties using more readily available data often found in soil surveys (such as particle-size distribution, bulk density, organic matter content, and others). Such indirect methods, now often referred to as PTFs as suggested by Bouma and van Lanen (1987, 1990), have been attempted for estimating water retention curve parameters, saturated hydraulic conductivity, the unsaturated hydraulic conductivity function, and other soil hydraulic parameters (Vereecken et al., 1990; Batjes, 1996; Lin et al., 1999b; Tietje and Hennings, 1996; van Genuchten et al., 1999a; Wösten et al., 2001; Shaw et al., 2000). Compared to other methods of estimating soil hydraulic parameters (e.g., pore-size distribution models and inverse methods), PTFs are inexpensive, easy to derive and use, and, in many practical cases, they provide good estimators for missing hydraulic parameters (Verhagen and Bouma, 1998; van Genuchten et al., 1999b; Wösten et al., 2001). Besides conventional regression or functional analyses, new techniques such as neural networks (Schaap et al., 2001), group methods of data handling (Pachepsky and Rawls, 1999), and CART (McKenzie and Jacquier, 1997) are increasingly being explored for developing PTFs using a growing number of large soil databases such as the NCSS databases, UNSODA (Leij et al., 1996), HYPRES (Wosten et al., 1999), WISE (Batjes, 1996), SoilVision (SoilVision Systems Ltd., 2002), and many others.

While various degrees of success have been achieved with different PTFs (Pachepsky et al., 1999; Wösten et al., 2001), limitations of existing PTFs remain. For example, the vast majority of existing PTFs are completely empirical, and limited efforts have been put into systematic probing of underlying mechanisms for

the existence of such functions. There is a tendency among soil scientists and others to estimate soil hydraulic functions by regression analysis in a given region, but efforts to apply PTFs derived from one area to soil hydrologic studies in other soil regions are futile (Kutílek and Nielsen, 1994). Only a few quasi-physical PTFs exist, such as those by Arya and Paris (1981), Haverkamp and Parlange (1986), and Arya et al. (1999), in which particle-size distribution is first translated into an equivalent pore-size distribution model and then further related to water retention curve. However, the flow system in the bundle of capillary tubes differs considerably from the water flow network in real-world soils (Miller and Miller, 1956; Beven and Germann, 1982). Thus, the practical application to field soils of these quasi-physical PTFs, based essentially on the Hagen–Poiseuille's law, is very limited. In addition, existing PTFs have not fully incorporated soil structure and land use information and have lacked scale and temporal considerations. As such, the accuracy, reliability, and utility of existing PTFs are constrained. In the mean time, the NCSS databases developed over the past century have been underused in addressing environmental issues. Interpretations and applications of the NCSS databases are challenges facing soil scientists in general and pedologists in particular. There are pressures on both pedologists and soil physicists/hydrologists to disseminate soil survey information and utilize it in a variety of applications (Simunek et al., 2003).

The combined efforts of pedologists, soil physicists, and hydrologists could open up new opportunities for the next generation of PTFs. For instance, five general categories of PTFs may be identified for potential improvement in estimating dynamic soil properties (Figure 35.7). PTF type I relates use-dependent

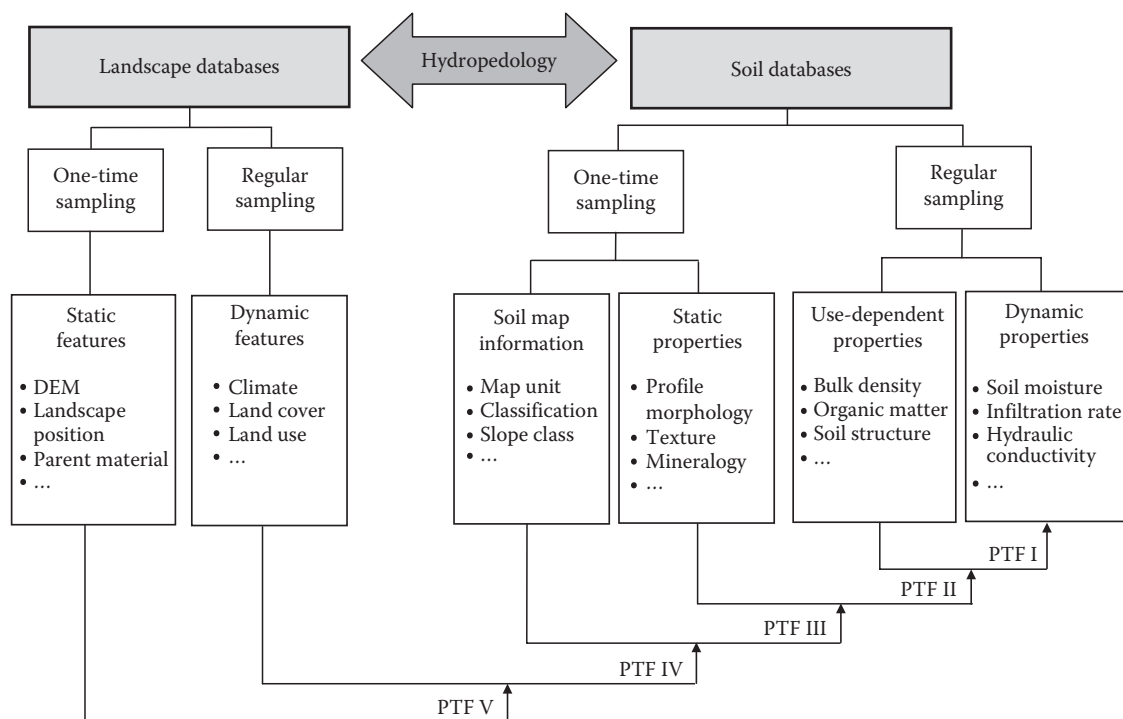

FIGURE 35.7 Five general categories of PTFs utilizing different types of input data for estimating dynamic soil properties. Landscape features such as DEMs, land use/land cover, and others serve as additional inputs to PTFs, hence connecting the pedon and the landscape scales.

soil properties to soil hydraulic information, both of dynamic nature requiring regular sampling. PTF type II includes relatively static soil properties that could be sampled only once into the prediction of dynamic soil properties. PTF type III further considers soil mapping and classification-related information to improve the prediction. Landscape features such as DEMs, land use/land cover, and others could serve as additional inputs in PTF type IV and V, hence connecting the pedon and landscape scales. It is likely that PTFs in combination with routine spatial information from soil survey, topography, and land use could improve the regional estimates of soil hydraulic parameters. In terms of land use and use-dependent soil properties, Droogers and Bouma (1997) suggested the terms "genoform" for genetically defined soil series and "phenoform" for soil types resulting from a particular form of management in a given genoform. Such distinction between major soil management types within the same soil series could potentially enhance PTFs that involve soil series and land use as carriers of soil hydraulic information. Realizing the importance of dynamic and use-dependent soil properties, the NCSS program is now considering the possible development of a dynamic soil properties database, which, once developed, would significantly facilitate the enhancement of PTFs.

Recent development in DSM coupled with earlier work on PTFs (Bouma, 1989; Bouma et al., 1999) has improved significantly the ability of soil science to transform itself from a semiquantitative to a quantitative discipline. This opportunity presents challenges at the same time, especially those related to understanding the scale dependency of hydrologic processes and their relation with spatial distribution of soil properties.

35.9 Digital Soil Mapping with Hydropedologic Concepts

In order to assess hydrologic function, soils and hydrologic processes must be fully understood within the context of the landscapes in which they occur. Soil serves as an interface between the solid and fluid envelopes, which dissipate mass and energy fluxes at the earth's surface (National Research Council, 2001). The majority of United States and World Soil Surveys are built upon soil–landscape model (Hudson, 1992), which recognizes the fact that in many landscapes, soil development occurs in response to the water movement through and over the landscape (Moore et al., 1993). This model limits the analysis of soil development at the scale where all the other soil-forming factors, namely, climate, parent material, organisms, and time, vary less compared to relief or topography. Jenny's model of five main soil-forming factors is expressed in the following equation:

$$S = f(cl, o, r, p, t. . .) \tag{35.3}$$

where S, soil, is considered to be a function of climate (cl), organisms (o), relief (r), and parent material (p) acting through time (t).

Aside from scientific value of the model, its widespread use may have been also a result of technical and practical considerations at the start of the Soil Survey Program related to purpose of the survey, scale, and resolution of the available spatial information. The use of Jenny's conceptual model leads to the development of maps relating soil pedogenesis and properties (Gessler et al., 1995) to landscape positions in a qualitative way (Walker et al., 1968; Furley, 1976; Daniels et al., 1985; Stone et al., 1985; Kreznor et al., 1989; Carter and Ciolkosz, 1991). The conventional soil maps reflect this approach in delineated soil polygon map units that represent the spatial continuum of soil properties with single values and ranges with no clear indication about their spatial distribution within map units. Soil scientists have recognized the inability to characterize the continuum and have compromised by providing polygon values with overlapping ranges for many soil properties. The use of this information in its current format presents a challenge for hydrologic modeling that requires a spatial continuum representation of soils and their properties (Libohova et al., 2010) as they modify material and energy fluxes at the earth's surface (Gessler et al., 1995). The challenge is to use hydropedologic principles to develop numerical and spatially realistic soil–landscape models useful for a variety of purposes beyond taxonomic classification (McSweeney et al., 1994). However, soil–landscape processes and relationships express themselves over a wide range of spatial and temporal scales, which reflect past climates, truncations by overriding processes, and perhaps feedback mechanisms (Malanson et al., 1990), and often exhibit different and complex scale-dependent variations (Butler, 1964; Beckett and Webster, 1971; Burrough, 1993; Wilding et al. 1994; Wilding and Drees, 1983). The scale dependency of soil variation indicates that more soil-forming factors may be at work at a particular location offering flexibility in incorporating other factors, especially location for explaining soil variability. Soil variability often relates well with terrain attributes, thus offering a potential use as spatial predictors of soil properties at specific locations (Gessler et al., 1995). With the dawning of GIS and powerful georeferencing tools, specific georeferenced spatial location has become a key consideration in the understanding of soils and their variability. A new formalization of the factors equation offered by McBratney et al. (2003) gives the following equation:

$$S_a = f(s, c, o, r, p, a, n) \tag{35.4}$$

where S_a is a set of soil attributes at a given location understood as a function of other observed soil attributes at either the present location or other proximal locations (s), climate (c), organisms (o), relief (r), parent materials (p), age or time (a), and spatial location or position (n). The formula offers an expansion of the equation discussed by Jenny (1941) to include soil properties observed at specific locations. It implies that, by using geostatistical tools, formal relationships between soils at measured distances can be developed to strengthen soil models. This is not a new idea; Jenny himself spent a great deal of time validating spatial soil relationships (Hudson, 1992), but it is a new formulation of the importance of spatial relationships and their power to help explain

soil properties. With available soil polygon data and soil point data, quantifiable terrain attributes (now often easily derived from DEMs in a GIS platform), and remotely sensed earth-surface-reflectance data, numerical analysis of soil–landscape relationships are possible to a much higher degree of accuracy and precision than ever before. The SCORPAN (S = soil, C = climate, O = organisms, R = topography, P = parent material, A = age and N = spatial position) model reflects the new emphasis on spatial location as a key attribute capable of providing predictive power in soil models. The increase recently in spatial resolution of DEMs and other spatial data coupled with the emerging of powerful terrain analysis software and geostatistical tools has provided an opportunity for soil scientists and digital soil mappers to numerically characterize soil–landscape models to develop raster-based predicted soil maps and soil property maps (Ryan et al., 2000). Soil–landscape model provides the appropriate scale for DSM to characterize soil variability as attributed to soil–water movement and distribution. This means that when climate, parent material, vegetation, and time are relatively constant, topography can explain the majority of differences in patterns of soil distribution. Topography itself is not the differentiating factor. However, topography controls water movement, which in turn affects pedogenesis. The use of terrain attributes as derived from topography captured by DEM provides the means to quantitatively represent the spatial distribution of soils and their related properties.

As previously discussed in the scale dependency of soils for modeling section, environmental modeling and management require explicit and quantitative spatial prediction of soil and landscape attributes (Gessler et al., 1995). Spatial variability affects hydrologic response over a wide range of scales (Sayfried and Wilcox, 1995; Robinson and Sivapalan, 1997) and is characterized as either stochastic and/or deterministic depending on the scale and the hydrologic process. This, in turn, means that any hydrological model has to represent soil model input parameters related to the scale of the research question, which can only be accomplished through DSM. Physically based distributed hydrologic models utilize spatially distributed inputs such as topography, soil type, and vegetation that in theory could provide a better description of hydrological processes (Bathurst and O'Connell, 1992). However, the amount of data input requirements could constitute a disadvantage for the physically based hydrologic models compared to lumped parameter models (Sayfried and Wilcox, 1995), and it may not always lead to better model predictions of hydrologic processes (Beven, 1987; Loague, 1990; Wicox et al., 1990; Anderson et al., 1992; Grayson et al., 1992).

The development of high-resolution spatial data and increase in computing power has led to demands for higher-resolution input data for hydrological modeling, especially for physically based distributed hydrology models. However, problems related to the limits of detail representation and parameterization of subgrid scale processes (within pixel) will still remain (Beven, 2001) and need to be addressed in the context of multiscale heterogeneities to identify their broad scale or general patterns (Sivapalan, 2005). The discussion on hydrological parameters, multiscale heterogeneities, and their scale dependency pattern

manifestation is closely related to the stochastic versus deterministic representation of spatial variability of hydrological parameters. This definition resonates with the soil–landscape model that could be considered as the "deterministic length scale" for describing the spatial variability of soils and their related properties. Both trends are found in every parameter, and the dominance of one or the other is scale dependent as previously discussed, which means that the future efforts in characterizing spatial variability of soil properties in a raster format as input to hydrological models should consider other scales in addition to the scale of soil–landscape model. This approach utilizing DSM is not limited only to hydrology and can be applied to other areas like ecology and environmental sciences and would lead to the development of soil property maps that emphasize their functions in relation to the process being hydrological, ecological, or other applications (Forman, 1995).

New spatial technologies (including GPS and GIS) have allowed the soil survey to georeference all of their recent soil samples as part of their soil characterization database (Soil Survey Staff, 2009) developed by the Soil Survey Laboratory (SSL), National Soil Survey Center. This database provides access to the raw characterization data, including morphology, saturated hydraulic conductivity, depth of soil, and bulk density. Using the source data to produce continuous maps of hydrologically important soil parameters should more clearly link real measurements with landscape position and provide a better set of soil parameters for hydrologic modeling. Given the recent developments in digital technologies like GIS, GPS, and spatial terrain analysis software coupled with DSM, spatially distributed raster-based predicted soil property maps for modeling can now be produced (McKenzie and Gallant, 2007; McKenzie and Ryan, 1999), validated, and tested with hydrologic models.

35.10 Conclusions

In 2001, the U.S. National Research Council (NRC, 2001) released a report entitled Basic Research Opportunities in Earth Science. This report highlighted the need for understanding the earth system and identified the pedosphere as an area crucial to the critical zone function. Hydropedology can contribute significantly to the holistic study of the earth's critical zone because of the key roles that soil and water play together in the critical zone's evolution and functioning. Understanding and quantifying the interactions between water and soil is critical for understanding multiscale ecosystem functions that sustain life. The future land use planning and use of natural resources under changing climate require multidisciplinary approaches where prediction and forecast based on quantifiable metrics must be achieved. Wilding and Lin (2006) pointed out a common agenda where soil science has been identified as a major stakeholder in the growing interests in bio- and geosciences as highlighted in the NRC (2001) report. This agenda was to (1) broaden constituencies beyond traditional partners; (2) expand focus in the near-surface "critical zone" to include food security, food safety, ecosystem management, biosphere sustainability, environmental protection, and urban

environment; (3) enhance fundamental knowledge of earth systems that is more systematic, interdisciplinary, dynamic, and process oriented; (4) identify early warning systems of natural hazards and resource degradation; and (5) develop joint research and education partnerships that attract coupling of public and private support. As described in this chapter, hydropedology provides one important mechanism where linking disciplines with a common theme can provide the avenue for a greater understanding of complex and dynamic interactions between the pedosphere and the hydrosphere.

Subaqueous Soils

Mark H. Stolt

Martin C. Rabenhorst
University of Maryland

36.1 Introduction and Historical Development of Subaqueous Soil Concepts

One of the new frontiers in soil science that has come into focus over the past two decades has been the study of subaqueous soils. Although the concept has appeared in the literature at times (Kubiëna, 1953; Muckenhausen, 1965), only recently have these substrates received recognition in the United States and as such are now accommodated under the definition of soils (Soil Survey Staff, 1999). Under the new definition, soils may occur in permanently flooded or ponded environments with water depths up to approximately 2.5 m (Soil Survey Staff, 1999).

Previous opposition to the concept of subaqueous soils was primarily focused upon the idea that subaqueous substrates are not, in fact, soils but sediments. The ruling dogma was that by definition a soil must be able to support the growth of plants (Soil Survey Staff, 1975). Thus, the essential absence of higher plants in many subaqueous environments excluded these substrates from the pedologic realm. A secondary issue was related to the defining boundaries of a soil. The first edition of *Soil Taxonomy* (1975) stated that the upper limit of soils is "…. air or shallow water." In this sense, "shallow water" was meant to exclude soils permanently under water. Thus, these materials were also excluded from being soil by their permanent inundation. Over the 25 years that spanned the development of the second edition of *Soil Taxonomy* (Soil Survey Staff, 1999), pedological thinking continued to evolve such that pedologists began distancing themselves from their agricultural roots with a loosening of the link between the definition of soils and the growth of plants. Rather, pedologists began to emphasize what had already become deeply entrenched as the foundation to the taxonomy itself, namely, the formation of horizons resulting from those generalized pedogenic processes described by Simonson (1959). For example, Bockheim (1990, 1997) and Campbell and Claridge (1987) showed that in the harsh-cold climate of Antarctica, where higher plants are not able to grow, soil horizons were still observed as a result of pedogenic processes (i.e., additions, losses, transfers, and transformations). Thus, the idea that these areas should be recognized as soils was gaining support among the pedologic community, even though they were not necessarily capable of supporting the growth of higher plants.

Much of the credit for the emergence of subaqueous soils as a field of soil science has to be given to Dr. George P. Demas. The story goes that the concept formed in George's mind as he was standing on the edge of the marsh in Maryland that he was mapping, and looking down into the shallow tidal water of Sinepuxent Bay, he posed the question "Why should we stop mapping here?" He began to consider that such submersed aquatic vegetation as eelgrass (*Zostera marina*) and widgeongrass (*Ruppia maritima*) was rooted in these substrates (Figure 36.1) and as he began to closely examine them observed what could be construed as pedogenic horizons. Soon afterward he published his paper "Submerged Soils: A New Frontier in Soil Survey" in *Soil Survey Horizons* (Demas, 1993). Over the next 6 years under the guidance of Dr. Martin Rabenhorst, Demas further developed the ideas and concepts for the characterization, formation, and mapping of subaqueous soils in his PhD dissertation (Demas, 1998).

The works of Demas led to a number of additional studies that form the basis for most of the discussion in this chapter.

FIGURE 36.1 Eelgrass meadow growing on a shoal in 1.5 m of water. The soil supporting the eelgrass is a sandy skeletal Typic Haplowassent. (Photo Jim Turenne.)

In particular, the most important findings or accomplishments included in the work and dissertation were as follows:

- Subaqueous soils form as a result of the generalized processes of additions, losses, transfers, and transformations (Demas and Rabenhorst, 1999). This led to a change in the definition of soil to include substrates that are permanently under significant water (approximately 2.5 m) and that show evidence of pedogenesis (Soil Survey Staff, 1999).
- Bathymetric maps could be constructed to use as a soil survey base map and identify subaqueous landforms in a manner analogous to the subaerial landforms that soil scientists had been studying for most of the past century (Demas and Rabenhorst, 1998).
- Similar soils occurred or formed on similar landforms. Therefore, the "soil–landscape" paradigm typically used to map subaerial environments could be applied to the mapping subaqueous soils, and, thus, specific soil–landscape relationships began to be documented for the coastal lagoons of the Mid-Atlantic United States.
- The establishment of the first official soil series for subaqueous soils: Demas,* Sinepuxent, Southpoint, Tizzard, Trappe, and Whittington.

Kubiëna (1953) was the first to use the term "subaqueous soils" to describe permanently inundated soils. Those soils composed of layers and forming in low-energy subaqueous environs were classified into four groups (Kubiëna, 1953). Most of the focus was on soils having considerable soil organic matter: dy, gyttja, and sapropel; terms often applied to substrates in limnological studies (Saarse, 1990). Horizon sequences were typically A, AC, and C regardless of the soil type. Dy soils formed below water columns that were acidic, nutrient poor, and having high concentrations of soluble organic compounds. These soil materials have a gel-like form indicative of amorphous organic matter. Gyttja forms in subaqueous soils rich in nutrients. The majority of the materials are coprogenic in origin, having a loose arrangement

(Jongerius and Rutherford, 1979) typical of high n-value soil materials (low bearing capacity; Soil Survey Staff, 2010). These subaqueous soil materials have also been referred to as sedimentary peat, coprogenous earth, or limnic materials (see Fox, 1985; Soil Survey Staff, 2010). Subaqueous layers that contain various amounts of more or less unrecognizable organic debris that are enriched in sulfides were termed sapropels. Most of these sulfides are Fe-monosulfides or pyrite in the solid form or hydrogen sulfide gas as recognized by the rotten egg smell. Colors are typically black that changes to gray upon drying.

The classification of subaqueous soils by Kubiëna (1953) was cited in the national soil classification system in Germany (Muckenhausen, 1965), but there is no evidence that these soils were the focus of any serious investigation. A decade later, although he did not elaborate nor focus much on what he called "subaquatic soils," Ponnamperuma (1972) did affirm that these soils forming under water reflected "horizon differentiation distinct from sedimentation." Nevertheless, between the publication of this paper and the time when Demas began to focus on these systems more than two decades later, apparently little attention was paid to subaqueous soils.

36.2 Soil Genesis in Subaqueous Environments

In addition to the generalized model of soil genesis (additions, losses, transfers, and transformations) described by Simonson (1959), pedologists have often invoked the state factor equation of Jenny (1941) to describe and conceptually model the formation of soils. While Jenny's model has limitations, it recognizes the contributions of various soil-forming "factors." In considering the genesis of subaqueous soils, similarities to the processes and factors described by Jenny (1941) were recognized, but significant differences were also noted. The generalized model for estuarine sediments of Folger (1972) was noted where he described their origin as being derived from source geology (G), bathymetry (B), and hydrologic condition (H) (flow regime).

$$S_e = f(G, H, B) \qquad (36.1)$$

The concepts of both of these previous equations were joined, with some further modifications, into a state factor equation to describe the formation of subaqueous soils (Demas and Rabenhorst, 2001).

$$S_s = f(C, O, B, F, P, T, W, E) \qquad (36.2)$$

where
    S_s is subaqueous soil
    C is the climatic regime
    O is organisms
    B is bathymetry
    F is flow regime
    P is parent material
    T is time
    W is water column attributes
    E is catastrophic events

---

* Originally proposed as Wallops but posthumously named Demas following the untimely death of innovator Dr. George P. Demas in December 1999.

Climatic regime (C) was not included in Folger's equation and does not include precipitation as in Jenny's model. The climatic component in this model primarily represents temperature. Temperature, for example, will affect the rate of organic matter decomposition (and other biogeochemical reactions).

Organisms (O) was also not included by Folger and represents the role that biota play in subaqueous pedogenesis. As an example, the burrowing of benthic organisms (essentially irrigating their burrows with oxygenated water) often contribute to the development of light-colored, surface horizons, as well as the obvious contributions of plant carbon to the upper soil horizons.

Bathymetry and flow regime (B and F) replace relief (R) in Jenny's equation. The catena concept per se is not applicable in a permanently submersed environment because relief or topograph do not play the same role as in subaerial soils. Bathymetry contributes to the effects of internal and wind-generated waves on the subaqueous soil surface. Flow regime helps to shape underwater topography and accounts for differences in the energies associated with currents and tides. Together, these two factors (B, F) essentially play the same genetic role as relief does in subaerial soil environments.

Parent material (P) was a factor in both the equations of Folger and Jenny and explains the effect of the source material on subaqueous soil profile attributes. For example, subaqueous soils that form in areas where they receive barrier island washover materials are predictably sandy textured.

Time (T) of course represents the amount of time available for the expression of subaqueous soil attributes.

Water column attributes (W) was not included in either Jenny's or Folger's equations and has been added to include variations in the chemical composition of the water column that could have an impact on subaqueous soil characteristics. Those subaqueous soil profiles developed in freshwater regions or fresh portions of estuaries will likely be significantly different than those formed in more saline or brackish environments where sulfate is available for reduction to sulfide and the potential formation of solid phase sulfide minerals. Similarly, the dissolved oxygen levels in the water column could dramatically impact the formation or the thickness of light-colored, oxidized, surface horizons.

Catastrophic events (E) is included in this equation to account for the possibility that subaqueous soil profiles may be dramatically impacted by major storm events or other uncontrollable or unknown factors. The effects of storms or modest hurricanes, however, do not seem to cause wholesale alterations to large areas of subaqueous soils.

36.3 Mapping, Research, and Agency Efforts

Subaqueous soils research and mapping projects have been completed or are in progress along the eastern seaboard of the United States from Maine to Florida and along the Gulf Coast in Florida and Texas (Table 36.1). Projects have covered a range of topics including mapping protocols, soil–landscape relationships, carbon sequestration, soil variability, pedogenesis, use and

management interpretations, and relationships between subaqueous soils and submerged aquatic vegetation (SAV) and water quality. Study and mapping areas have primarily concentrated on estuarine areas such as coastal lagoons and shallow water embayments (Figure 36.2). In response to mapping efforts, regional and national subcommittees within the National Cooperative Soil Survey have been established to advance national mapping standards and procedures for subaqueous soils. New parent material and landscape–landform terms have been added to the *National Soil Survey Handbook* (NCSS, 2005), and *Soil Taxonomy* has been revised to accommodate the classification of subaqueous soils. In Rhode Island, a partnership was developed (MapCoast, 2009) among Federal agencies such as US. Environmental Protection Agency (USEPA), USDA-Natural Resources Conservation Service (NRCS), National Oceanic and Atmospheric Administration (NOAA), state-level agencies, and university researchers and scientists to apply the information provided in subaqueous soil investigations to coastal resource issues and problems. The MapCoast partnership is a consortium dedicated to multidisciplinary mapping of coastal underwater resources, including bathymetry, habitat, geology, soils/sediment, and archeological resources in shallow waters (August and Costa-Pierce, 2007). NOAA is redesigning their classification system for shallow subtidal habitats (similar to the Cowardin et al. (1979) system for wetlands) and including a subaqueous soils component (Madden et al., 2008).

36.4 Methods for Characterizing Subaqueous Soils and Mapping Their Distribution

One of the big hurdles in investigations of subaqueous soils and mapping their distribution was the lack of methodologies for identifying, sampling, characterizing, and mapping subaqueous soil properties and their distribution. Discussions on topics such as collecting bathymetric data, using a vibracore, collecting soil samples under water, and handling subaqueous soil samples for subsequent laboratory analysis were essentially absent from the soil literature.

36.4.1 Creating a Subaqueous Terrain Map

Landscape units provide a first approximation of the distribution of soils on the landscape and offer an objective delineation of soil types. Numerous studies have emphasized the importance of landscape components for predicting and explaining soil distributions (Jenny, 1941; Ruhe, 1960; Huddleston and Riecken, 1973; Stolt et al., 1993; Scull et al., 2005). Subaqueous landscapes are fundamentally the same as subaerial systems and have a discernable topography from which subaqueous landforms and landscape units may be identified. However, because of the overlying water, submerged landscapes and landforms cannot be identified easily using standard methods such as stereo photography or visual assessment of the landscape. Therefore, identification and delineation of subaqueous landscape units is somewhat more complicated than that of terrestrial landscapes, and development of subaqueous topographic maps is a critical first step toward delineating subaqueous landscape units.

Bathymetric data (water depths) are used to produce a contour or bathymetric map from which subaqueous landforms can be identified and delineated to begin the soil survey. Thus, x, y, and z coordinates are necessary to create a contour map. XY locations are obtained with a differential GPS receiver (DGPS) with submeter accuracy.

Water depths can be determined in a number of ways. The quickest approach is to use a fathometer or bottom profiler. The transducer portion of the profiler is attached to the boat just below the water line. As the boat moves along the water, depths are obtained and stored in the fathometer computer or a device such as laptop. Demas and Rabenhorst (1998) reported that soundings were collected at approximately $4 \, km^2 \, h^{-1}$. Soundings should be collected essentially along fairly evenly spaced transects that are perpendicular to the shoreline. The depths are corrected by adding the depth between the water surface and bottom of the transducer and correcting for changes in the tide while the data are being collected.

Tide corrections are made from data collected from tide gauges operating at the same time that the bathymetric data are being

collected. One to three tide gauges are generally required depending upon the size of the area of interest and the complexity of the tidal cycle within the estuary. Tide gauges should be surveyed in from United States Geological Survey (USGS) benchmarks. Tide corrections can be made in a number of ways. Most simple tidal fluctuations can be corrected using equations developed from the tidal cycles and applied via a spreadsheet. Complicated corrections may require the use of software designed for the purpose.

There has been some discussion and some attempts to use LIDAR (light detection and ranging) to obtain bathymetric data more rapidly. The SHOALS (U.S. Army Corps of Engineers) bathymetry system uses a scanning, pulsed, infrared (1064 nm), and blue–green (532 nm) laser transmitter where the depth of water is determined from the difference in return times of the two beams and knowing the speed of light in water. Optimally, this system can be used to measure water depth from 0 to 40 m with a vertical accuracy of 20 cm. While this may have promise, there are a number of limitations that can be especially problematic including the following: (1) water clarity limits the ability of light to penetrate to the bottom; (2) high surface waves and heavy fog decrease the depth penetration of the lasers; and (3) heavy vegetation and fluid mud influence the depth penetration of the lasers. Also, in many systems where the maximum water depth is only a few meters, a resolution of 20 cm may not be adequate. Hopefully, advances will continue, so that more rapid acquisition of bathymetry becomes possible.

Bathymetric data should be reviewed to remove aberrant depths and aberrant XY locations. A number of software programs are available to construct topographic maps. As an example, an ArcView TIN model was created using the bathymetric soundings and a hard break line (depth = 0) consisting of the wetline from recent orthophoto. The TIN was converted to a GRID (10 m pixel size). The land–water interface observed from the orthophoto wetline was used as a mask to set all land-based pixels to NODATA. The bathymetric GRID was smoothed by applying a 3 pixel radius averaging filter, and contours were created from the smoothed bathymetric GRID. Although the TIN model was used in our example here, other modeling approaches such as kriging have been applied to bathymetric data to create topographic maps.

Using the fathometer from a boat is limited to water depths greater than 50 cm. In areas where there is considerable tidal fluctuation (a meter or more tidal fluctuation), shallow water may be profiled at high tides. If tidal fluctuations are less, surveying of the shallow water may be necessary. This can be done with a survey grade GPS that records elevations real-time kinetic (RTK), a total station, or an all-purpose elevation rod and level. This approach can also be used to validate contour maps created from bathymetric data.

36.4.2 Landscape and Soil Delineation

Landscape unit boundaries provide the first approximation of the distribution of soils over the landscape. Landscape attributes such as slope, microrelief, surface shape, and geographic proximity to other features, and location help define landforms and landscape unit boundaries. Landscape unit boundaries are hidden beneath the water cover in the subaqueous environment and need to be deciphered from contour maps. Landforms and units such as coves, submerged beaches, shoals, and washover fan flats and slopes are some common examples found in many estuaries (Figure 36.3; NCSS, 2005). In some cases, these features can be observed in aerial photographs that penetrate the water, but in general, a contour map illustrating slope breaks is necessary to define the boundaries on each unit.

Identifying the soil types within a landscape unit is done through reconnaissance efforts and transects. The same criteria used to separate mapping units in subaerial soils can be used in subaqueous soils. Tools such as a Macaulay peat sampler, bucket auger, and tile probe are effective in providing soil samples and data for identifying soil types. Peat samplers work well in high n-value (soft, low-density) soil materials, low-energy environments. In areas where low n-value mineral soils dominate, a bucket auger can be used to sample the upper 75 cm of the soil. Some soil scientists use a sleeve with an inside diameter slightly larger than the diameter of the auger to maintain an auger boring location and to minimize slumping of sandy materials into the auger hole. Samples collected in the bucket auger are often transferred to a vinyl tray or gutter on the boat for description and possible sampling. A floating tube with the tray strapped to the tube can work in the case of wading and mapping. Tile probes can be used to find depth to bedrock or similar consolidated or semiconsolidated materials. Percentages of boulders and large stones can also be estimated with the tile probe. Side-scan sonar images, or video footage across proposed mapping units, may aid in proper placement of boundaries and provide spatial data regarding the distribution of stones and boulders extruding from the soil and into the water column.

Just as in subaerial soil mapping, map unit purity and variability need to be addressed. The most common approaches are using random points or transects to assess variability. Studies of soil variability within the landscape units (Demas, 1998; Bradley and Stolt, 2003; Osher and Flannagan, 2007) demonstrate that the concept (common to subaerial landscapes) that soil type follows landscape form (Hudson, 1992) also holds for subaqueous soils (Table 36.2). For example, Bradley and Stolt (2003) reported that 11 of the 12 map units that were used to map the subaqueous soils in a coastal lagoon had a taxonomic purity (based on the subgroup taxonomic level) above criteria used for delineation of the traditional consociation map units used in most USDA-NRCS soil surveys (Soil Survey Division Staff, 1993).

One of the criticisms of inventorying subaqueous soils is that these environments are considered "ever-changing, unstable, shifting sands." Although some areas such as flood–tidal delta landscapes are quite dynamic, Bradley and Stolt (2002) showed that a detailed 1950s NOAA bathymetric map (NGDC, 1996) of the coastal lagoon (Ninigret Pond) was essentially no different than a bathymetric map created 50 years later. With the lifespan of a soil survey on the order of 25–30 years, subaqueous soil surveys should provide descriptions and interpretations for two to three decades of most areas having subaqueous soils (Table 36.3).
FIGURE 36.3 Examples of landscape units within a coastal lagoon. The barrier island complex (BIC), islands (I), and mainland are subaerial system. The tidal marsh-intertidal complex is sometimes subaqueous and sometimes subaerial. The flood-tidal delta (FTD), lagoon bottom (LB), washover fan (WF), washover-fan slope (WFS), lagoon channel (LC), mainland cove, and mainland submerged beach landscape units are subaqueous systems. The inlet brings in water from the open ocean on high tides and flushes the lagoon during out-going tide. Contour lines are for the subaqueous areas only have a 50 cm interval.

TABLE 36.2 Examples of Landscape Unit, Parent Material, and Soil Type Relationships from a Rhode Island Coastal Lagoon

Landscape Unit	Parent Materials	Typical Soil Subgroup Classification[a]
Lagoon bottom	Silt, fine sand, and organic material	Typic Sulfiwassents
Washover fan flat	Holocene sand	Typic Fluviwassents
Flood–tidal delta flat	Holocene sand	Typic Psammowassents
Washover fan slope	Holocene sand	Sulfic Fluviwassents
Flood–tidal delta slope	Holocene sand	Fluventic Psammowassents
Mainland submerged beach	Glacial fluvial sand and gravel	Typic Haplowassents
Barrier cove	Silt, fine sand, and organic material over glacial fluvial sand and gravel or Holocene sand	Typic Sulfiwassent
Mainland shallow cove	Holocene sand over glacial fluvial sand and gravel	Haplic Sulfiwassents
Midlagoon channel	Glacial fluvial sand and gravel	Typic Haplowassents
Barrier submerged beach	Glacial fluvial sand and gravel	Typic Haplowasssents
Shoal	Glacial fluvial sand and gravel	Typic Haplowassents
Mainland cove	Silts, fine sand, and organic material over buried organic material	Thapto-histic Sulfiwassents

36.4.3 Sample Collection for Characterization of Typifying Pedons

In high n-value materials, a relatively undisturbed half-core (5 cm diameter) can be collected using a Macaulay peat sampler, which is an excellent tool for providing samples for description and characterization. One limitation is that samples collected with a peat sampler are a bit small, which when coupled with the fact that the materials that can be sampled with the peat sampler have a low density, their dry mass is quite small. Thus, for characterization and descriptive purposes it may be necessary to take multiple adjacent samples if a Macaulay peat sampler is employed. High n-value materials can also be collected in a core barrel. A handle for pushing the core barrel in and pulling it out is attached to the barrel and weight (usually one or two persons lean on the handle) is added to push the core barrel into the soft materials. Several people are usually needed to pull the sample out.

Vibracore sampling is the most effective approach to obtain minimally disturbed samples for detailed description and sampling of typical pedons. A vibracore rig consists of an engine, a cable, and a vibracore head (Lanesky et al., 1979). The engine creates a high frequency, low amplitude vibration. The vibration is transferred through a cable to the vibracore head that is bolted to the top of core barrel or tube. This vibration essentially liquefies the soil materials in a thin zone immediately adjacent to the

tube, enabling the core barrel to penetrate into the soil materials. Weight is often added to the top of the core barrel to assist in pushing the core barrel into the soils. Vibracores come in a variety of forms from small, lightweight, and portable to large heavy machines.

Core barrels are generally made out of 7.5–10 cm inside diameter aluminum pipe (irrigation pipe). Some barrels are made out of polycarbonate (these are clear and light but also six to seven times more expensive than aluminum). Core barrel lengths should be as long as the soil to be sampled, plus water depth, and an extra 50 or 60 cm.

In many sampling systems, a core catcher is attached to the cutting end of the barrel. The catcher keeps the soil from sliding out of the barrel when the core is removed from the soil. Other systems rely on a rubber plug inside the barrel that rises up as the barrel is pushed into the soil. The plug maintains a short, nearly airtight space just above the sample to minimize disturbance. This approach also minimizes the suction of the sample out the bottom of the core when the core is removed.

A 2 m core of subaqueous soil that is collected in several meters of water is generally quite heavy and difficult to pull out of the soil. Thus, in most vibracore systems a tripod is set up with a winch or chainfall on the top to extract the core from the soil. The tripod is set up over an opening in the bottom of the sampling vessel. In most cases, a pontoon boat is used for sampling with a vibracore. Sampling is done through an opening (60 cm × 60 cm) in the deck ("moon pool"). The tripod setup can also be placed over a 2 m × 2 m barge that is towed behind the boat. An opening is cut in the middle of the barge. These barges are built from floating dock Styrofoam that is encased in marine plywood.

36.4.4 Subaqueous Soil Sampling and Description

Standard descriptive terminology as outlined in the *Soil Survey Manual* (1993), and by the National Soil Survey Lab (Schoeneberger et al., 2002), and horizon designations outlined in the *Keys to Soil Taxonomy* (2010) should be used to describe subaqueous soils. Samples collected with a Macaulay or bucket auger can be described and sampled immediately.

Cores collected with a vibracore can be sampled and described on the boat or returned to the lab and kept in cold storage prior to sampling. Keeping the samples in cold storage may not be adequate enough to inhibit sulfide oxidation entirely. Cores are extracted from the barrels by cutting the barrels lengthwise on both sides and removing the half barrel. Electric shears designed to cut metal are the best option. A circular saw can also be used to cut through most of the thickness of the barrels and a razor knife used to complete the cut. Prior to using the razor knife, the shards of aluminum or plastic should be whisked away.

36.4.5 Sample Analysis

Most sample analysis can be made following standard procedures outlined in the *Soil Survey Laboratory Methods Manual* (Burt, 2004). Certain soil properties will be affected by the

subaqueous environment, and laboratory procedures should be conducted with this in mind. Many subaqueous soil horizons (especially those collected from brackish or coastal environments) contain sulfides that may oxidize upon exposure to air. If samples are meant to be collected for classification purposes, treatment of the samples to avoid oxidation of the sulfides is critical. The most common approach is to immediately transfer the sample to a labeled bag, press out an air trapped in the bag, and put the sample on ice in a cooler. If the soil materials appear to be very reactive (unstable), or the amount of time between sampling and return to the lab is extended, pressurized nitrogen gas can be used to sparge the bags to remove oxygen prior to sealing. If deemed necessary, liquid nitrogen can be applied to the bag in the field to immediately freeze the sample after which it should be placed on ice.

Sulfides, salts, and shell fragments are the most important to consider when analyzing the soil and are worth noting. The presence of sulfides in the soils has been noted above and should be accommodated. Measurements of sulfides are not well documented in soil survey publications. Thus, if this characteristic is to be measured, consideration should be given to the numerous methods to measure chromium reducible and acid volatile sulfides (see Bradley and Stolt, 2006; Payne, 2007). Particle-size distribution analysis may need to be altered to accommodate for the weight and flocculation capability of salts. Samples can be washed to remove salts using dialysis tubing. Carbonates in shell fragments can be an issue in measuring organic carbon and should be considered when organic and calcium carbonate carbon is being determined.

36.5 Classification of Subaqueous Soils

Soil classification is much different than traditional sediment classification, where the substrate is termed mud, silty sand, muddy sand (Fegley, 2001), or other somewhat subjective class, and the focus is often on the upper portions of the profile. The soil classification approach offered in *Soil Taxonomy* is more comprehensive and addresses the larger soil profile. For example, a sediment classification of silty sand (e.g., see Fegley, 2001) could be better described using *Soil Taxonomy* as a coarse-silty over sandy skeletal, mixed, Typic Sulfaquent soil. This soil classification conveys that the upper portion of the soil has <18% clay and >70% silt-sized particles; the lower soil materials (to a meter depth or more) are sandy with >35% gravels or larger particles; the silt and sand-sized particles are not dominated by a particular mineral; and that there are enough sulfides within 50 cm of the soil surface that when the soil materials are allowed to oxidize the pH drops to below 4. Such additional knowledge could be important for decisions regarding the use and management of a portion of the estuary.

The latest version of *Keys to Soil Taxonomy* (Soil Survey Staff, 2010) includes taxa within Entisols and Histosols ("Wassents" and "Wassists") to accommodate subaqueous soils. The formative element "wass" is from the German word for water, "wasser" (Ditzler et al., 2008). Criterion for identifying both suborders is a

positive water pressure at the soil surface for at least 21 h each day in all years. The intent of the definition is to identify soils that are inundated everyday, every year, with no exceptions for periodic short- or long-term drought cycles. In certain areas with large tidal fluctuations, such as northern Maine in the United States, soils are inundated with 1–2 m of water everyday with the exception of a few hours at low tide. The 21 h minimum is proposed to allow for short daily exposure of these subaqueous soils.

Six great groups within Wassents are included keying out in the order: Frasiwassents, Psammowassents, Sulfiwassents, Hydrowassents, Fluviwassents, and Haplowassents (see Figure 36.4, e.g., profiles). Freshwater subaqueous soils key out as Frasiwassents based on an electrical conductivity of a 5:1 ratio of water to soil of <0.2 dS m^{-1}. Subaqueous soils that have sandy textures throughout the upper meter are Psammowassents. Sulfiwassents have at least 15 cm of sulfidic materials within the upper 50 cm of the soil. Soils with high n values (low bearing capacity) classify as Hydrowassents. Those soils with an irregular decrease in organic carbon with depth key out as Fluviwassents. Subgroup taxa include Sulfic, Lithic, Thapto-histic, Aeric, Psammentic, Fluventic, Grossic, Haplic, and Typic. With the exception of Grossic, all of these apply in a similar manner to previous applications in other taxa. Grossic is used to identify subaqueous soils that have very thick layers with high n values.

(a)   (b)

FIGURE 36.4 (a) Vibracore profile of a Haplic Sulfiwassent from a shallow mainland cove. The tape shows 10 cm increments. Note the clam krotovina from 30 to 50 cm (C/A horizon). The white pieces in the krotovina are shell fragments. At 120 cm, there is a change in parent material from the Holocene aged estuarine sediments to the Pleistocene outwash sand and gravels. (b) Vibracore profile of a Sulfic Fluviwassent. The soil was collected from a washover-fan slope. Note the many buried A horizons that represent storm surges. The buried A horizon starting at a meter represents the upper part of a previous Typic Sulfiwassent prior to encroachment of the washover fan over the lagoon bottom landscape unit.

Subaqueous Histosols are classified as Wassists. There are three great groups: Frasi-, Sulfi-, and Haplo-wassists. The Frasiwassists have low electrical conductivity (<0.2 dS m⁻¹); Sulfiwassists have >15 cm of sulfidic materials within 50 cm; and Haplowassists are all other Wassists. Three subgroups are proposed: Fibric, Sapric, and Typic, depending on the dominant type of organic materials present. Examples of Wassent–landscape relationships are shown in Table 36.2. The *World Reference Base* (WRB) FAO (2006) has taxa similar to those proposed for *Soil Taxonomy*. WRB's Subaquatic Fluvisols correlate to Wassents, and the Subaquatic Histosols correlate to Wassists.

36.6 Applications of Subaqueous Soil Information

Shallow-water coastal habitats, including coastal lagoons, shallow bays, and estuarine areas, are highly valued and heavily used resources. Almost two-thirds of the worldwide population currently lives in coastal areas (Trenhaile, 1997), and recent demographic studies suggest that in the next 25 years 75% of the U.S. population will live in close proximity to the coast (Bush, 2004). As subaqueous soil science progresses, a wide range of use and management interpretations are expected to be developed for use with estuarine subaqueous soil maps (August and Costa-Pierce, 2007; Surabian, 2007; Payne and Turenne, 2009). These interpretations will aid in coastal, estuarine, and marine restoration, ecosystem management, and conservation efforts. For example, subaqueous soils information can be used to assist in the restoration of SAV and shellfish; identifying shellfish aquaculture sites; design and placement of shoreline protection, docks, and moorings; and identifying subaqueous soils that are of beneficial use from dredging (Demas and Rabenhorst, 1999; Bradley and Stolt, 2003; Bradley and Stolt, 2006; Surabian, 2007). Since subaqueous soil investigations are a relatively new focus in pedology, and most of the subaqueous soil efforts have concentrated on developing field and laboratory methodology, few studies have concentrated on interpretations. Thus, the breadth of information relating soil type with the use and management of these resources is quite limited.

36.6.1 Dredging and Dredge Placement

Dredging of subaqueous soils is a common practice to deepen navigable waterways and to replenish beaches. Subaqueous soils often have layers or horizons where sulfides have accumulated in subaqueous soils as a result of sulfidization. When the sulfide-bearing soils are dredged and placed in the subaerial environment, sulfides oxidize releasing sulfuric acid, lowering the pH, and creating acid sulfate soils (Fanning and Fanning, 1989). Acid sulfate soils may persist for a number of years and are uninhabitable for plants and animals. If deposited near water, these acid sulfate soils can also create runoff that is toxic to aquatic systems (Demas et al., 2004).

To test for sulfides and for taxonomic purposes, subaqueous soils are allowed to oxidize in a moist environment. In general,

those soil materials that after at least 16 weeks of moist incubation reach pH values <4 are considered to have sulfidic materials (Soil Survey Staff, 2010) and are potential acid sulfate soils. Whether these soils reach the incubation pH of potential acid sulfate soils is dependent upon a number of factors such as the buffering capacity, rate and extent of acid production, weathering, and leaching due to environmental factors are not considered in the laboratory approach. For example, during a moist incubation, a small amount of sulfide would lower the pH in a sandy soil with low organic carbon because of the limited amount of buffering capacity. In such soils, the amount of acid produced would be much less than a soil with a similar incubation pH but a higher buffering capacity because of a finer texture or greater organic matter levels. In a natural setting, a small amount of acid could potentially leave a sandy, minimally buffered soil very quickly as the acidity generated by oxidation would be washed out of the system as a result of precipitation and leaching. In contrast, acid sulfate conditions may remain for decades in a fine-textured, buffered soil. Thus, understanding a number of soil parameters is critical to identifying the subaqueous soils that can be deposited in a subaerial environment as dredged materials and maintain conditions conducive for plant growth and a safe environment.

36.6.2 Water Quality

Estuarine ecosystem integrity and sustainability has received tremendous interest in recent years. These interests are being driven by concerns over the negative effects of rapid urbanization and related anthropogenic activities on the coastal environment. As the use of these natural resources has increased, the most urbanized estuaries have been ecologically compromised and common ecosystem functions and values are being lost. Obvious signs of these degraded environmental conditions are accumulations of metals and other contaminants, an increase in emerging diseases and algal blooms (Harvell et al., 1999), and anoxia related fin and shellfish kills (RIDEM, 1998, 2003). Most of these issues are related to poor water quality.

Water quality has traditionally been used in coastal areas as an indicator of the overall health of an estuary (Stevenson et al., 1993; Glasgow and Burkholder, 2000; Granger et al., 2000). Because water quality can fluctuate with tidal cycles and seasonal and yearly weather changes, water quality trends are difficult to predict or to use as a reliable indicator of extended changes in the health of an estuarine system (D'Avanzo and Kremer, 1994; Cicchetti et al., 2006). Soil properties and characteristics develop in response to the environment, making subaqueous soils a potential long-term indicator of the degree that these ecosystems have become degraded (Germano and Rhoads, 1988; Valente et al., 1992). Such an indicator would allow estuary management teams to target particular estuaries for conservation, protection, and restoration of resources based on soil survey information. Understanding the degree and spatial distribution of the degradation is critical to managing coastal estuaries for any number of functions and values, especially aquaculture and restoration of commercially important shellfish populations.

Redox conditions in a soil have important impacts on chemical processes that occur in the soil such as denitrification, changes in forms of iron, manganese, or sulfur, and the solubility of heavy metals (Tomaszek, 1995; Teasdale et al., 1998). The decomposition of organic matter by microbes fuels the redox reactions in soil. Oxygen is the strongest oxidizing agent in aqueous systems and acts as an electron acceptor during microbial decomposition. In subaqueous systems, however, oxygen can quickly be depleted and other electron acceptors are used by the microbes. These other electron acceptors include nitrate, manganese, iron, sulfate, and carbon dioxide. Each species, respectively, is reduced at a lower range of redox potentials depending on the pH (Bohn et al., 1979). These processes produce a vertical profile of decreasing redox potential with depth as each oxidizing agent is reduced until all organic matter has been decomposed (Teasdale et al., 1998).

The first of these boundaries, where all oxygen has been depleted or reduced, is generally known as the redox boundary, the redoxocline, or the redox potential discontinuity (RPD) (Knox, 1986; Teasdale et al., 1998; Hinchey and Schaffner, 2005). The depth of the RPD can be influenced by the grain size, organic matter content, temperature of the soil, as well as the movement and dissolved oxygen content of water above the soil surface (Knox, 1986). A redox potential gradient found in subaqueous soils often includes the oxidized surface layer where oxygen is still present in the interstitial water, a zone of transition where other species are being reduced, and a sulfide zone that is totally anaerobic, H_2S is prevalent, and redox potentials are very low (Knox, 1986). This zonation plays an important role in determining layers in which chemical processes involving organic carbon, nitrogen, and sulfur occur and can serve as an indication of estuary health.

36.6.3 Submerged Aquatic Vegetation

One part of the definition of soil is the ability of soil to support rooted plants in a natural environment (Soil Survey Staff, 1999). Dense beds of SAV (or seagrass) are often found in subtidal estuaries. Unlike macroalgal species, which anchor themselves to a substrate, seagrasses are rooted vascular aquatic plants in which roots serve both structural and nutrient uptake purposes (Barko et al., 1991). One of the most important interpretations from an inventory of subaqueous soils may be seagrass restoration. SAV such as eelgrass provides nursery habitat for economically important fin and shellfish and is important for sediment and nutrient filtering, nutrient cycling, and buffering wave effects. In many estuaries, aerial coverages of seagrass beds have severely declined over recent years. Therefore, seagrass restoration has become a focus of many coastal managers. Seagrass revegetation and restoration projects cost on the order of $100,000 per acre, but few of these projects have been successful. It is highly likely that the projects fail because of site selection. Seagrass revegetation sites are commonly located where past seagrass meadows had been, not at sites where present soil conditions are optimum for success. However, loss of seagrass tends to result in erosion of the subaqueous soils. Thus, soils within areas that previously supported seagrass may be significantly different following the loss of vegetation and subsequent erosion. A detailed knowledge of the relationship between subaqueous soil properties and SAV is essential for improving the success of seagrass revegetation efforts. An understanding of the seagrass–subaqueous soil system will help resource managers identify the sites where revegetation efforts can be most successful (Bradley, 2001). Few studies have looked at these relationships. Bradley and Stolt (2006) examined subaqueous soil–eelgrass relationships in a northeastern U.S. coastal lagoon. Similar studies need to be made across regions with a focus on the predominant seagrass species and the breadth of tidal ranges and gradient of temperatures.

36.6.4 Carbon Storage and Sequestration

With the concern with global warming mounting as a result of increasing greenhouse gas emissions, there is a significant interest in carbon storage and sequestration in soil systems. These interests have led to numerous studies focused on soil carbon for various land types and covers. Although forested and emergent wetlands have been well studied in regard to carbon sequestration, carbon sequestration and storage studies have largely overlooked estuary soils as important carbon sinks (Chmura et al., 2003; Thom et al., 2003). Considering that the shallow subtidal component may occupy as much as 90% of the estuary, these areas likely represent a significant and unaccounted for sink for carbon. Little is known, however, regarding the contribution of the shallow subtidal portions of the estuaries to the regional carbon stocks.

Geologic studies focused on estuarine and oceanic substrates have included organic carbon as a parameter inventory; however, most of these studies focus on surficial soil samples with the goal of understanding the origin and formation of petroleum (Hedges and Oades, 1997). Utilizing a pedologic approach, it is possible to quantify the organic carbon content of the subaqueous soil with depth, where it is actually stored, not just within the soil surface. Once soil organic carbon is determined for specific sites within an estuary, it will be possible to scale up to a regional or global scale in order to better determine the estuarine soils importance as a global carbon storage unit. Jespersen and Osher (2007) and Payne (2007) investigated the carbon storage capabilities of subaqueous soils in the Taunton Bay estuary in Maine and three embayments in Rhode Island, respectively. In both studies, a soil survey of the estuary was completed as a component of the study to relate organic carbon storage to soil–landscape unit. In addition, carbon pools to a depth of a meter in subaqueous soils were compared to their adjacent subaerial upland and wetland soils. The estuarine soil organic carbon pools were found to be equal to, and in some cases greater than, subaerial soil organic carbon pools. Payne (2007) reported higher energy, sandier soil–landscape units, such as shoals and shorefaces, had lower carbon pools than the lower energy soil–landscape units such as bay bottoms. Similar relationships were observed by Jespersen and Osher (2007).

The studies made by Jespersen and Osher (2007) and Payne (2007) were focused on northeastern tidal embayments. Little is

known regarding the expansive coastal lagoons of the Atlantic coast or Gulf of Mexico estuarine subaqueous soils. Carbon pools and sequestration rates in freshwater subaqueous soils are also unknown. Future studies should be designed and implemented to investigate these subaqueous soil systems.

36.6.5 Moorings and Docks

With any body of water there are typically structures built or deployed to secure boats. The foundation for these docks or mooring (permanent anchor that boats are secured to in a harbor) are the subaqueous soils. Thus, how well the mooring or dock functions is dependent upon subaqueous soil type. The bearing capacity or n value of the surface and near surface soils is one of the most important characteristics. Surabian (2007) examined relationships between subaqueous soils and moorings and found that mushroom anchors work best in high n-value soils. These moorings sink into the low bearing capacity soils and are kept in place by surface area and suction forces. Deadweight anchors are best suited for low n-value soils or soils dominated by coarse fragments (Surabian, 2007).

36.6.6 Shellfish

Subaqueous soils are critical to the structure and function of many of the plants and animals in the estuarine ecosystem and are the foundation for commercial shellfish production and aquaculture. Worldwide the aquaculture industry continues to develop and expand. Although the economics are difficult to quantify worldwide, the value of aquaculture products per acre typically far exceed those of traditional agriculture. For example, in 2007 the average value of Rhode Island aquaculture products (oysters and clams) was $32,000 per hectare (Alves, 2007). Considering the cash value of these aquaculture products, developing an understanding of the relationships between the submerged landscape, the subaqueous soils, and the growth and productivity of aquaculture species such as clams, oysters, scallops, and mussels is essential. To date, very little information is available regarding the relationships between shellfish productivity and subaqueous soil type.

The few works that have studied aquaculture–soil type relationships have focused on clams (Pratt, 1953; Pratt and Campbell, 1956; Wells, 1957; Grizzle and Lutz, 1989; Grizzle and Morin, 1989). These studies investigated clam abundance and shell-size growth rates with environmental factors such as soil type. Soils in these studies were fairly crudely characterized (i.e., sand or mud); however, most of the studies found a relationship between growth and particle size existed. In general, increases in fines (muds, silt, and clay) were associated with retardation in growth of clams. Grizzle and Lutz (1989) concluded that substrate type is important in some instances but seston flux (the amount of suspended particulate matter including plankton and organic detritus that passes by over a given period in the water column) is more important. Since sandy substrates typically have higher energies, the seston flux is often higher relative to finer textured soils.

Thus, current views on the shellfish–soil relationship are that the increased growth associated with sandier substrates in the earlier studies has been reinterpreted to be a secondary result of sandier soil being associated with higher current velocities (Rice and Pechenik, 1992). This suggests that subaqueous soil type may not directly relate to shellfish growth, but may serve as a surrogate for identifying areas of favorable seston fluxes, and could thereby be used to predict areas of the subtidal estuary with the highest potentials for shellfish growth. A better classification of the soil that would come with a subaqueous soil survey (i.e., better than sands and muds) may prove a better predictor of shellfish growth and provide delineations for the best locations for aquaculture of clams and oysters.

36.7 Future Considerations for Subaqueous Soils

Although subaqueous soils have received occasional mention in the literature for more than 50 years, only in the past decade or so have these soils been investigated with any intensity or focus. The limited number of investigations to date suggests that additional mapping, characterization, and research is needed to better understand these soils. In the United States, nearly all of the subaqueous soils projects have been conducted on the eastern seaboard in coastal waters. The same resource, habitat, and ecosystem service issues that have begun to be addressed from a pedological perspective in eastern U.S. estuaries also need to be examined in other shallow subtidal habitats as well as freshwater systems. As we have shown, the application of subaqueous soils investigations to addressing environmental and ecosystem questions related to restoration, aquaculture, carbon accounting, water quality, etc. is dependent upon an inventory of the subaqueous soil resources. The soil survey landscape-level models developed for mapping soils of embayments and lagoons need to be tested further in other Atlantic shallow subtidal habitats and then in other areas of the country and of the world. Concerted efforts should be made to conduct widespread subaqueous soil survey projects that are founded on established standards and protocols such as those used in the National Cooperative Soil Survey. These subaqueous soil resource inventories should be conducted and published at a scale that will be useful to resource managers attempting to balance both use and conservation of aquatic ecosystems that are heavily taxed and impacted as increasing populations choose to inhabit areas near the water.

37.1 Introduction

The current explosion in computation and information technology comes with vast amounts of data and tools in all fields of endeavor. This has motivated numerous initiatives around the world to build spatial data infrastructures aiming to facilitate the collection, maintenance, dissemination, and use of spatial information. Soil science potentially contributes to the development of such generic spatial data infrastructure through the ongoing creation of regional, continental, and worldwide soil databases. The principal manifestation is soil resource assessment using geographic information systems (GISs), that is, the production of digital soil property and class maps with the constraint of limited relatively expensive fieldwork and subsequent laboratory analysis.

The production of digital soil maps ab initio, as opposed to digitized (existing) soil maps, is moving inexorably from the research phase (Skidmore et al., 1991; Favrot and Lagacherie, 1993; Moore et al., 1993) to production of maps for regions and catchments and whole countries. The map of the Murray–Darling basin of Australia (Bui and Moran, 2001) comprising some 19 million $250\,\text{m} \times 250\,\text{m}$ pixels or cells and the digital Soil Map of Hungary (Dobos et al., 2000) are the most notable examples. The progress and development of digital soil mapping is marked by adoption of new mapping tools and techniques, data management systems, innovative delivery of soil data, and methods to analyze, integrate, and visualize soil and environmental data sets (Grunwald, 2009).

McBratney et al. (2000) reviewed pedometric methods for soil survey and suggested three resolutions of interest, namely, $>2\,\text{km}$, $20\,\text{m}$–$2\,\text{km}$, and $<20\,\text{m}$, corresponding to national to global, catchment to landscape, and local extents. Table 37.1 provides an overview with five resolutions of interest. The third one (D3) that deals with subcatchments, catchments, and regions is the one that attracts the most attention. In the language of digital soil maps (Bishop et al., 2001), which differs from that of conventional cartography, scale is a difficult concept and is better replaced by resolution and spacing. D3 surveys, which in conventional terms have a scale of 1:20,000 down to 1:200,000, have a block or cell size from 20 to 200 m, a spacing also of 20–200 m, and a nominal spatial resolution of 40–400 m (see Table 37.1).

Unfortunately, the existing soil databases are neither exhaustive nor precise enough for promoting extensive and credible use of the soil information within the spatial data infrastructure that is being developed worldwide. The main reason is that their present capacities only allow the storage of data from conventional soil surveys, which are scarce and sporadically available.

The Netherlands has complete coverage at a nominal spatial resolution of 100 m. In France, on the other hand, a highly developed western economy, but with a large land area, only 26% of the country is covered at a nominal spatial resolution of 500 m and 13% at a nominal spatial resolution of 200 m (King et al., 1999). One third of Germany is covered with soil maps at a nominal spatial resolution of 10 m (1:10,000) but most of these are not yet digital (Behrens and Scholten, 2006). On the other hand, complete coverage of Germany at coarser resolutions (nominally 100 and 400 m) is available. It was projected that in 2010, 65% of Germany's soil maps will be digitized.

TABLE 37.1 Suggested Resolutions and Extents of Digital Soil Maps

Name	Approx. USDA Survey Order[a]	Nominal Resolution and Spacing (Pixel Size)	Resolution "loi du quart"[b]	Extent[c]	Cartographic Scale[d]
D1	0[e]	<(5 m × 5 m)	<(25 m × 25 m)	<(50 km × 50 km)	>1:5,000
D2	1, 2	(5 m × 5 m)–(20 m × 20 m)	(25 m × 25 m)–(100 m × 100 m)	(500 m × 500 m)–(200 km × 200 km)	1:5,000–1:20,000
D3	3, 4	(20 m × 20 m)–(200 m × 200 m)	(100 m × 100 m)–(1 km × 1 km)	(2 km × 2 km)–(2,000 km × 2,000 km)	1:20,000–1:20,0000
D4	5	(200 m × 200 m)–(2 km × 2 km)	(1 km × 1 km)–(10 km × 10 km)	(20 km × 20 km)–(20,000 km × 20,000 km)	1:200,000–1:2,000,000
D5	5	>(2 km × 2 km)	>(10 km × 10 km)	>(200 km × 200 km)	<1:2,000,000

[a] Soil Survey Staff (1993), Table 2.1.

[b] According to Boulaine (1980), the smallest area discernible on a map is 0.5 cm × 0.5 cm or one quarter of a square centimeter, hence the term "loi du quart." The USDA *Soil Survey Field Handbook* (Table 2.2) (Soil Survey Staff, 1993) quotes 0.6 cm × 0.6 cm. Both of these really refer to conventional map delineations, and resolution estimates based on these minimum areas should be regarded as very conservative.

[c] Calculated as minimum resolution times 100 (pixels) up to maximum resolution times 10,000 pixels.

[d] Digital soil maps are defined by their resolution and spacing—which here we equate with pixel size—the cartographic scale is calculated as 1 m/(side length of 1,000 pixels), assumes that the smallest area discernible is 1 mm × 1 mm. Conversely, the resolution (ρ) of a 1:100,000 conventional map can be calculated as, $\rho = 1/\chi \times \lambda = 100,000 \times 0.001 = 100$ m if we consider the smallest area resolvable on a map (λ), with representative fraction χ, to be 1 mm × 1 mm. It could be argued that the minimum resolution is the size of 2 × 2 pixels.

[e] This resolution was suggested by Dr. Pierre C. Robert, University of Minnesota, for applications in precision agriculture.

The situation in larger countries such as Australia and Brazil is much worse. In Australia, for example, prior to Moran and Bui's (2002) work, the Murray–Darling Basin, Australia's most important agricultural region comprising some 14% of the land area, had 50% coverage at 500 m and 3% at 200 m. In Brazil, the country is uniformly covered by the Soil Map of Brazil and the Agricultural Suitability Map of Brazil at a nominal spatial resolution of 10 km, exploratory soil maps by the RADAM/EMBRAPA Solos project (1:1,000,000 or nominally 2 km) and Agroecological Zoning (diagnosis of environmental and agro-socioeconomic features, nominally 4 km or 1:2,000,000).

The main reason for this lack of soil spatial data is simply that conventional soil survey methods are relatively slow and expensive. Furthermore, there is a worldwide crisis in collecting new field data in general that leads some to be very pessimistic about future developments in conventional soil surveying. To address this situation, current spatial soil information systems have to extend their functionalities from the storage and the use of digitized (existing) soil maps to the production of soil maps ab initio. This is the aim of digital soil mapping, which can be defined as the creation, and population of spatial soil information systems by the use of field and laboratory observational methods coupled with spatial and nonspatial soil inference systems (Lagacherie and McBratney, 2006).

Thus, digital soil mapping refers to the production of spatial soil databases, based on soil observations combined with environmental data through quantitative statistical relationships. In that sense, digital soil mapping is not simply digitizing existing soil maps and is more than just producing paper maps. There are other terminologies such as "predictive soil mapping" (Scull et al., 2003) that refers to the production of digital soil maps, and "environmental correlation" (McKenzie and Ryan, 1999) that is an aspect of the spatial soil prediction function.

Digital soil mapping uses a range of technologies allowing for more accurate and efficient prediction of soil properties through optimal sampling strategies, rapid analysis of soil properties, and rapid acquisition of environmental variables over a large extent. Combined with pedometric techniques, it can provide the best prediction of soil properties at the required resolution with associated uncertainties. Digital soil mapping can be thought as a means for modernizing and systematizing traditional soil survey.

In this chapter, we review various approaches with numerous examples from the literature, which are largely seen as special cases of the approach suggested here. First, we trace the development of the quantitative ideas and methods over the last 60 or so years.

37.2 Brief Review of Approaches to Soil Spatial Prediction

Hudson (1992) contended that soil survey is a scientific strategy based on the concepts of factors of soil formation coupled with soil–landscape relationships. Hewitt (1993) pleaded for the need for explicitly stated, but not necessarily quantitative, models for soil survey. Such models may be knowledge based (Bui, 2004). In this view, soil maps are representations of soil surveyors' knowledge about soil objects. In this chapter, we argue in favor of quantitative predictive models.

37.2.1 Jenny

Recalling Jenny's famous equation (Jenny, 1941), which he intended as a mechanistic model for soil development,

$$S = f(c, o, r, p, t, \ldots) \qquad (37.1)$$

implicitly

S stands for soil

c (sometimes *cl*) represents climate

o represents organisms including humans

r represents relief

p represents parent material

t represents time

some have asserted that it cannot be solved; nonetheless, since Jenny published his formulation, it has been used by innumerable surveyors all over the world as a qualitative list for understanding the factors that may be important for producing the soil pattern within a region. Numerous researchers have taken the quantitative path and have tried to formalize this equation largely through studies of cases where one factor varies and the rest are held constant. So quantitative climofunctions, topofunctions, etc. have been developed. Much of this work was done before sophisticated numerically intensive statistical methods became available. Here are some brief examples.

c (sometimes *cl*): Climofunctions were the ones most developed by Jenny in his 1941 book. Jones (1973) found relationships between carbon, nitrogen, and clay and annual rainfall and altitude in West African savanna using linear and multiple linear regression. Simonett (1960) found a power–function relationship between mineral composition of soil developed on basalt in Queensland and annual rainfall.

o: There seems less development of organofunctions, many believing that the principal organofunction or biofunction, that of vegetation, is dependent on soil rather than the converse. Noy-Meir (1974) found relationships between vegetation and soil type in S.E. Australia. The other principal organofunction, the anthropofunction, has only been recently quantified—much of the work on soil degradation and soil quality is evidence of the effect of humanity on soil. The classic work of Nye and Greenland (1960) is an early quantitative example.

r: The relationship between soil and topographic factors has been evident at least since Milne's paper (Milne, 1935). Quantitative topofunctions are manifold. For example, Furley (1968) and Anderson and Furley (1975) found a piecewise linear relationship between organic carbon, nitrogen, and pH of surface horizons and slope angle for profiles developed on calcareous parent materials around Oxford in England.

p: Quantitative lithofunctions have not been developed often, perhaps due to a difficulty in recognizing and quantifying the dependent and independent variables. Barshad (1958) quantified mean clay content as a function of rock type.

t: Some consider this the only truly independent variable (but if that is the case why is space not also included?). Chronofunctions are often theoretical or hypothetical rather than observed. Hay (1960), however, found an exponential relationship between clay formation and time for soil developed in volcanic ash on the island of St. Vincent, as would be expected from first-order kinetics.

A lot of this early quantitative work was very well summarized by Yaalon (1975). Many of the relationships found are not linear. It should be remembered that the aim of these investigations was to understand soil formation and not necessarily to predict soil from the other factors.

Recognition of interactions between the soil-forming factors is potentially important because it is one possible source of detailed soil pattern. It is difficult to find work that considers such interactions explicitly. Webster (1977) perhaps came closest with his canonical correlation studies of sets of soil properties and environmental factors. From this work, he suggested, for example, that soil will reflect a strong interaction between topography and lithology particularly on upper slope positions, but this will be time dependent. Odeh et al. (1991), using closely related methods, made similar findings.

37.2.2 Geographic and Neighborhood (or Purely Spatial) Approaches

Since the late 1960s, there has been an emphasis on what might be called geographic or purely spatial approaches, that is, soil attributes* can be predicted from spatial position largely by interpolating between locations of soil observation. Another way of thinking about this is as a *neighborhood law* expounded first perhaps by Lagacherie (1992), but is the basis underlying the soil combinations of Fridland (1972) and also of soil geostatistics (Giltrap, 1977), etc. Generally, we can consider the soil at some location (x, y) to depend on the geographic coordinates x, y and on the soil at neighboring locations $(x + u, y + v)$, that is,

$$s(x, y) = f((x, y), s(x + u, y + v)), \qquad (37.2)$$

the dependence usually being some decreasing function of the magnitude of u and/or v.

This approach arose originally out of the need for spatial prediction to make soil maps, and because of a failure to obtain prediction from the soil-forming factors largely because the quantitative variables describing these factors were not readily available to do such predictions. These purely spatial approaches are almost entirely based on geostatistics and its precursor trend-surface analysis, although thin-plate smoothing splines have been suggested and used occasionally (Laslett et al., 1987; Hutchinson and Gessler, 1994). Exact-fitting splines do not perform well (Laslett et al., 1987; Voltz and Webster, 1990).

37.2.2.1 Geostatistics and Related Methods Trend Surfaces: $s(x, y) = f(x, y)$

Trend surfaces are low-order polynomials of spatial coordinates. Several applications have been reported in the literature. Davies and Gamm (1969) applied this technique to soil pH values from the county of Kent in England. Edmonds and Campbell (1984) described the average annual soil temperatures at locations within a network of stations from Virginia and neighboring states with a third-degree polynomial that explained 71% of the observed variation. On the other hand, Kiss et al. (1988) found

---

* Soil attributes is a general term to mean that which can be attributed to the soil by measurement or inference, for example, soil properties like pH, or classes like a soil profile class, or the presence or the absence of a soil horizon class.

that the spatial pattern of ^{137}Cs activity in well-drained, native noneroded soil in the agricultural portion of Saskatchewan was complex and could not be adequately described by a second-order trend surface. There appears to be no literature on trend surfaces for soil classes; nevertheless, Wrigley (1978) has made an attempt to map the probability of the occurrence of soil classes. Spatially, trend surfaces are rather simplified "unnatural" representations, and more complex spatial patterns often need to be modeled.

$$\text{Kriging—}s(x, y) = f(s(x + u, y + v)). \tag{37.3}$$

It was recognized that more complex spatial patterns could be accommodated by treating soil variables as regionalized variables using the methods of geostatistics, particularly various forms of kriging. The papers by Burgess and Webster (1980a, 1980b; Webster and Burgess, 1980) are probably regarded as the most seminal. These kriging methods, reviewed by Burrough (1993), Goovaerts (1999), and Heuvelink and Webster (2001) could deal with continuous soil properties and classes, could give estimates for blocks or pixels of varying size, and moreover could estimate uncertainty.

$$\text{Co-kriging—}s(x, y) = f(s(x + u, y + v), \{c, o, r, p, t\}(x, y)). \tag{37.4}$$

It was recognized early in the development of soil geostatistics that soil could be better predicted if denser sets of secondary variables (spatially cross-) correlated with the primary variable were available; this technique is called co-kriging. In the early co-kriging studies (McBratney and Webster, 1983; Vauclin et al., 1983; Goulard and Voltz, 1992), these ancillary variables were other soil variables, indicating that other soil variables are themselves useful predictors of soil. Later, with the advent of GIS and improved technology, co-kriging was performed with detailed secondary data sets of environmental variables derived from digital elevation models and satellite images (Odeh et al., 1994, 1995).

37.2.2.2 Jenny and Geography—Corpt or Clorpt: $s(x, y) = f(\{c, o, r, p, t\}(x, y))$

An alternative spatial prediction strategy to the purely geographic approaches was developed in the early 1990s, although there were precursors. In these studies, the state-factor equation was put explicitly into a spatial framework, and the factors were also observed in the same spatial domain. This approach probably resulted from the advent of the first GISs, and also possibly as a pedological response to geostatistics. It seems to be based on a much earlier 1D example of using environmental (terrain, representing *r*) attributes for soil prediction, namely, that of Troeh (1964) and Walker et al. (1968). Probably the first of its kind, Aandahl (1948) quantitatively relates landscape attributes to soil properties. He derived the distribution of N based on slope length. Troeh (1964) analyzed the elevation data from two catenas and derived slope and profile curvature. He then plotted the slope gradient and profile curvature and found that the soil drainage classes could be distinguished by paraboloid of

revolution equations. Walker et al. (1968) used slope, curvature, aspect, and distance from the local summit, in combination with multiple linear regression to predict soil morphological properties such as A horizon depth, depth to mottling, and carbonates along a transect. An early, perhaps the first, 2D example is Legros and Bonneric (1979), based on earlier work by Legros (1975). They described a soil–environment relationship using various factors (altitude, slope, exposure, and parent material) that were observed on a 500 m grid-cell basis to predict the degree of podsolization in Massif du Pilat of France, and mapped it digitally at a resolution of 500 m. The prediction was achieved by a kind of taxonomic distance relative to reference sites. This was done well before the advent of formal GIS.

The GIS-based studies started at the beginning of the 1990s. Terrain analysis had improved and secondary rasterized layers, providing a kind of complete enumeration of the area could be put in GIS. The soil observation points were intersected with the layers of secondary data, a model fitted by various means, and then the model was used to predict all other locations on the raster. Moore et al. (1993) gave the first 2D example using a set of terrain attributes derived from a digital elevation model on a 15 m grid to predict continuous soil properties such as A horizon thickness and pH for a small catchment in Colorado. Odeh et al. (1994) did a similar study in South Australia. Skidmore et al. (1991) predicted forest soil classes in New South Wales from layers of natural vegetation data (representing *o*) and terrain attributes on a 30 m grid. Bell et al. (1992, 1994) predicted soil drainage class from terrain data, and Lagacherie and Holmes (1997) predicted soil classes in the Languedoc using layers of lithological and terrain data. Favrot and Lagacherie (1993) foreshadowed this as a general approach for making soil class maps.

For quantitative prediction purposes, this has been called the "*clorpt*" or "*corpt*" equation (McBratney et al., 2000). Some people have termed the approach "environmental correlation" (McKenzie and Austin, 1993). McKenzie and Ryan (1999) used environmental correlation associated with stratigraphy, digital terrain models and gamma-radiometric survey, respectively, to predict soil properties in Australia. Ryan et al. (2000) reviewed the concepts and applications of spatial modeling using the "environmental correlation" approach and used it to predict forest soil properties at the landscape level.

For predicting soil classes, S_c, or soil properties, S_a, often only a subset of the five soil-forming factors has been used, for example, when information from a digital elevation model is available,

$$\begin{aligned} S_c &= f(r), \quad \text{e.g., Bell et al. (1992)} \quad \text{or} \\ S_a &= f(r), \quad \text{e.g., Moore et al. (1993),} \end{aligned} \tag{37.5}$$

or relief and a lithology map,

$$S_c = f(r, p), \quad \text{e.g., Lagacherie and Holmes (1997),} \tag{37.6}$$

or relief and vegetation,

$$S_c = f(r, o), \quad \text{e.g., Skidmore et al. (1991).} \tag{37.7}$$

37.2.2.3 Combinations: Clorpt (or Corpt) and Kriging

Alert readers will have noted that there has been a certain similarity and convergence between the co-kriging and the environmental correlation approach. Some workers recognized this in the mid-1990s and combined the two in what is generically known as regression-kriging (Knotters et al., 1995; Odeh et al., 1995). In this approach, "*clorpt*" is used to predict the soil property of interest from environmental variables, and kriging is used on the residuals. Bourennane et al. (1996) used kriging with external drift, which is related to regression-kriging but only allows for linear relationships between the variable of interest and the environmental variables (the external drifts).

37.2.3 Predicting Soil Attributes from Other Soil Attributes: $s_1 = f(s_2)$

As noted above, some of the co-kriging studies (McBratney and Webster, 1983; Vauclin et al., 1983) showed that soil could be predicted from other soil attributes. This observation in itself is not very useful unless there are much denser secondary variables available. Remote (e.g., gamma radiometrics) and proximal sensing (e.g., electromagnetic induction) offer this possibility. This becomes increasingly important because Phillips (2001) gives several examples where "*clorpt*" apparently does not work, particularly at fine resolutions. This suggests that for predictive purposes, s (for soil) should be added to the "*corpt*" list.

37.2.4 Some Brief Conclusions

From this brief review, we see that

1. Quantitative relationships have generally been most easily found between soil and topography but there is evidence of quantitative relationships with the other four soil-forming or soil-altering factors.
2. In general, the relationships cannot be assumed to be linear.
3. Little work has been done on interactions between factors.
4. Soil can be spatially predicted from geographic position using a variety of techniques.
5. Soil can be predicted from other soil attributes at the same location.
6. Soil can be predicted from itself, other soil attributes, and environmental attributes at neighboring locations.

37.3 The Scorpan Model

McBratney et al. (2003) generalized and formalized the digital soil mapping approach using a Jenny-like formulation not for explanation but for empirical quantitative descriptions of relationships between soil and other spatially referenced factors with a view to using these as soil spatial prediction functions. This is called the "*scorpan*" model, which can be written as follows:

$$S_c = f(s, c, o, r, p, a, n) \quad \text{or} \quad S_a = f(s, c, o, r, p, a, n), \quad (37.8)$$

where
S_c is soil classes
S_a is soil attributes

There are seven factors:

1. s—soil, other properties of the soil at a point
2. c—climate, climatic properties of the environment at a point
3. o—organisms, vegetation or fauna or human activity
4. r—topography, landscape attributes
5. p—parent material, lithology
6. a—age, the time factor
7. n—space, spatial position

Soil is included as a factor because soil can be predicted from its properties, or soil properties from its class or other properties. The s refers to soil information either from a prior map, or from remote or proximal sensing or expert knowledge. Implicit in this are the spatial coordinates x, y (and probably not z) and an approximate or vague time coordinate $\sim t$. This time coordinate can be expressed as "at about some time t." So explicitly, for example,

$$S_c[x, y, \sim t] = f(s[x, y, \sim t], c[x, y, \sim t], o[x, y, \sim t],$$
$$r[x, y, \sim t], p[x, y, \sim t], a[x, y], [x, y]). \quad (37.9)$$

Each factor will be represented by a set of one or more continuous or categorical variables, for example, c by average annual rainfall and average annual temperature or climate class.

We shall not consider the direction of causality. For example, many reckon vegetation to be dependent on soil and we could write $o = g(S)$, where o is set of vegetation classes or percentage cover of a species, g is some arbitrary function, and S is a set of soil classes or attributes. For our purpose, we could write $S = g^{-1}(o)$, where g^{-1} is the inverse function of g, $S = g^{-1}(o) = f(o)$. We stress that the approach in general is not theoretical, and it is largely empirical—where there is evidence of a relationship we use it. Clearly, although we do not require causality, we should be mindful of potential problems of nonuniqueness if g is not a monotonic function, as well it might be if S is say topsoil pH and o is the number of plants of a particular species per unit area.

A general soil prediction model would be

$$S(x, y, z, t) = f(Q), \quad (37.10)$$

where Q is predictor variable(s). Here we will consider some restrictions, in cases where S stands for $S(x, y, (z), t)$, that is, the soil class or attribute at some spatial location x, y, (z) and at some time t.

37.3.1 What Is *S*? Soil Classes *S*$_c$ or Individual Soil Attributes *S*$_a$

The model must be able to predict the probability of a set of classes, for example, for the case of five classes, say, A, …, E, the model would predict the probability vector (p[A], p[B], p[C], p[D], p[E]), for example, $S_c[x, y]$ = (0.01, 0.72, 0.01, 0.02, 0.25) along with some measure of uncertainty. The problem will generally consist of a preexisting soil class label (from some soil classification system) at each soil observation location and a set of colocated environmental variables. These are called the training data. This represents a supervised classification or supervised learning problem. (More rarely, unsupervised learning also known as numerical classification may be used on observed soil attributes to first generate the class labels.) The supervised learning rules are fitted using the training data and then used at other locations where only environmental variables are observed. Most prediction methods treat soil classes as "labels," and their prediction only considers the minimization of the misclassification error. Soil classes at any taxonomic level have taxonomic relationships between each other, and in some instances, the errors in prediction of certain classes are more serious than the others. Minasny and McBratney (2007a, 2007b) proposed the incorporation of taxonomic distance between the soil classes in the prediction.

The model should also be able to predict individual soil attributes S_a along with a measure of uncertainty. The S_a might be the value of a given soil attribute at a certain depth, for example, the clay content at 60 cm, that is, $S_a[x, y]$ = 310 g/kg, along with an uncertainty measure. Similarly to the class problem, this will generally consist of a measured soil attribute at each soil observation location and a set of colocated environmental variables. These are the training or calibration data. This represents a generic (multiple) regression problem. The generic regression equations or rules are fitted using the calibration data and are then used at other locations where only environmental variables are observed.

Heuvelink and Webster (2001) have discussed the merger of discrete and continuous models of spatial variation. Heuvelink (1996) suggested the mixed model of spatial variation, in which the soil property is treated as the sum of a global mean, a class-dependent deviation from the mean, and a spatially correlated residual. Prediction with this model boils down to kriging with an external drift (Delhomme, 1978), which in this case is a classification. Its main advantage is that it performs well over the whole range of spatial variation, from exclusively discrete realities. A more general interpretation of this kind of idea, and the one we use here, is that the external drift represents *f*() and can be any kind of function. The discreteness or continuity of *S* will depend on the magnitude and form of *f*(). In the Heuvelink (1996) case, the *f*() is a one-way analysis of variance model, a special case of a generalized linear model (GLM) (McCullagh and Nelder, 1983; Lane, 2002).

37.3.2 The General Approach

If we write the equation as *S* = *f*(*Q*) + *e*, then the general approach we shall use is to take some observations of *S* in the field at known locations [*x*, *y*] and fit some kind of function to a set of pedologically meaningful predictor variables *Q*, which will generally be raster data layers of size *M* in a GIS. Once the model is fitted at the *m* observation points, the prediction can be extended to the *M* points or cells in the raster thereby giving a digital map. The efficiency of the method relies on the fact that hopefully *m* ≪ *M*, and because *S* is much more difficult and expensive to measure than the *Q*. The success will depend on the following:

1. Having sufficient predictor variables observed everywhere or at least with a relatively high data density
2. Having enough soil observations (data points) to fit a relationship
3. Having functions *f*() flexible enough to fit a nonlinear relationship
4. Having a good relationship between the soil and its environment

Followed by a discussion of quantitative procedures for fitting *f*() in Section 37.3.3, we present some considerations concerning *e* in Section 37.3.4, and a review of previous studies in Section 37.3.5.

37.3.3 Form of *f*()

We will now discuss some forms of *f*(), most, but by no means all, of which have been or can be used for this kind of problem. For the sake of brevity, we shall not delve deeply into the mathematics of the methods. The advance in statistical learning techniques, enhanced by ongoing developments in data mining, has aided the use of different forms of *f*() in soil science. Recent developments and technical details of the statistical modeling have been recently and extensively reviewed by Hastie et al. (2009). When predicting soil classes, some kind of *supervised classification* will be used, and for soil attributes, some kind of *generic regression* will be used. These are now discussed.

37.3.3.1 Linear Models

Linear models include regression for predicting soil attributes and classification for predicting soil classes. Linear regression included in this section is linear models using ordinary or generalized least squares (GLS). Linear methods for classification include discriminant analysis.

37.3.3.1.1 Ordinary Least Squares

For multiple linear regression, the model is written as follows:

$$\mathbf{s} = \mathbf{Qb} + \mathbf{e}, \tag{37.11}$$

where
  s is the vector of response (predicted soil attribute)
  Q is the matrix of predictor variables
  b is parameter vector of the linear function
  The error component, **e**, represents the deviations of the model to the observed value

The parameter is usually solved using ordinary least squares (OLS), with assumptions that **e**

1. Are independently and identically distributed (independence assumption)
2. Have zero mean and finite variance (homoscedasticity assumption)
3. Are normally distributed (normality assumption)

OLS has been used widely in prediction of soil attributes, because of the ease of use and wide availability. The predictors are usually continuous variables; however, qualitative factors or discrete variables can also be integrated.

37.3.3.1.2 Principal Component Regression and Partial Least Squares

When a large number of correlated predictor variables is present (such as electromagnetic spectra), usually principal component analysis is used to produce linear combinations of the original inputs. Selected principal components are then used in place of the original predictors. Alternatively, partial least squares (PLS) (Martens and Naes, 1989) are developed, which constructs a new set of components as regressor variables that are linear combination of the original variables. Unlike principal component regression, which only uses a combination of the predictors, the components in PLS are determined by both the response variable(*s*) and the predictor variables.

Principal component regression and PLS have been used quite extensively in predicting soil attributes from the electromagnetic spectrum, especially in the near and mid-infrared ranges (e.g., Chang et al., 2001). This method may be necessary if the environmental covariates consist of hyperspectral imagery.

37.3.3.1.3 Linear Discriminant Analysis

Discriminant analysis (Fisher, 1936) is the seminal supervised learning technique. It has been applied in soil science for more than 70 years. Webster and Burrough (1974) used the method to allocate soil observations into existing classes. Henderson and Ragg (1980) employed a multivariate logistic method to assess the usefulness of soil properties for distinguishing between taxonomic units. The method was perhaps first used for digital soil mapping by Bell et al. (1992, 1994) who related soil drainage classes to landscape parameters and used the resulting discriminant functions for spatial predictions.

The theory is readily accessible in Webster and Oliver (1990) and Hastie et al. (2009). Triantafilis et al. (2003) generalized the theory to a fuzzy linear discriminant analysis. This considers the a priori membership of each individual to each of the classes.

37.3.3.2 Generalized Linear Models

GLMs extend the linear regression models to accommodate nonnormal response distributions (Hastie and Pregibon, 1992). The theory and applications in soil science have been reviewed by Lane (2002). Usually, to accommodate for nonlinearity, transformation of variable is introduced, GLM attempt to modify the model rather than transforming the data (Lane, 2002). GLMs have the assumption of independence between the response and predictor variables.

37.3.3.2.1 Prediction of Continuous Soil Attributes S_a

McKenzie and Austin (1993) used GLMs to predict soil attributes (clay content, CEC, EC, pH, bulk density, and COLE) using environmental variables (geomorphic unit, local relief, etc.) as predictors. Other examples include Odeh et al. (1995, 1997) and McKenzie and Ryan (1999) who used GLMs to predict nonnormally distributed continuous variables. In both of these cases, the GLM was used in preference to standard linear regression because of the nonnormal distribution of the response variable. Park and Vlek (2002) found that GLMs performed better than neural networks and regression trees in predicting soil attributes from environmental variables.

37.3.3.2.2 Prediction of Soil Classes S_c

Gessler et al. (1995) used GLMs to predict the presence or absence of a bleached A2 horizon using digital terrain information. In this case, a logit link function was used due to the binomial distribution. Campling et al. (2002) used logistic regression to model soil drainage classes from terrain attributes and vegetation indices as calculated from a Landsat TM image. Kempen et al. (2009) developed a logistic regression model for predicting soil groups in the Netherlands from DEM, groundwater maps, land cover, paleogeography, geomorphology, and soil maps. The model-building process was guided by pedological expert knowledge to ensure that the final regression model is not only statistically sound but also pedologically plausible.

37.3.3.3 Generalized Additive Models

Generalized additive models (GAMs) attempt to characterize the nonlinear effect, which is not considered in GLMs. GAMs have the form:

$$S = \alpha + \sum_{j=1}^{p} f_j(q_j) + e, \qquad (37.12)$$

where

α is the intercept
f_j is a nonparametric "smoothing" functions for predictor q_j
p is the number of covariates
e is the error

The smoothing functions can be splines, loess, kernel, and other, smoothers (Venables and Ripley, 1994). Smoothers fit the data locally, and crucial to the fit is the size of the local neighborhood, which is generally controlled by a smoothing parameter. The smoothing parameter controls the variance–bias trade-off. A large neighborhood produces estimates with low variance and potentially high bias, a small neighborhood produces the reverse effect (Hastie and Tibshirani, 1990).

The reported use of GAMs in the soil science literature has been minimal. One of the few studies has been Odeh et al. (1997) who compared GAMs with GLMs and linear regression for the prediction of organic carbon with digital terrain information as secondary information. GAMs were found to be superior. Bishop and McBratney (2001) used GAMs for mapping

of soil cation exchange capacity from environmental factors (terrain attributes, bare soil color aerial photograph, bare soil LANDSAT imagery, crop yield data, and soil apparent electrical conductivity).

37.3.3.4 Tree Models: Classification and Regression

Various implementations of decision trees (DT) or classification trees (CART) have been used to extract and apply knowledge about soil spatial patterns. Tree-based models are fitted by successively splitting a data set into increasingly homogenous subsets. The response variable can be either a factor (classification trees) or a continuous variable (regression trees), and the explanatory variables can be of either type (McKenzie and Ryan, 1999). Once the partitioning has ceased, the subsets are called terminal nodes. Each terminal node is typically assigned the label of the majority class. Splits, or rules defining how to partition the data, are selected based on information statistics that measure how well the split decreases impurity (heterogeneity or variance) within the resulting subsets (Scull et al., 2005). All possible organizations of explanatory variables into two groups are examined recursively to evaluate the effectiveness of each possible split.

Decision trees have found favor in digital soil mapping (DSM) because they can handle missing values, can use continuous and categorical predictors, are robust to predictor specification, and make very limited assumptions about the form of the regression model (Henderson et al., 2005).

Lark et al. (2007) expressed some reservations about overfitting with data mining methods such as regression trees unless the methods were evaluated against truly independent test data.

Henderson et al. (2005) concluded that regression trees had been widely adopted because they were robust, could handle continuous and categorical data, and were reasonably easy to interpret. The final trees are essentially binary keys with yes/no decisions based on a single class or parameter value at each node. This makes it easy to express the splitting rules in semantic terms that are easily understood and appreciated by human interpreters.

37.3.3.4.1 Prediction of Continuous Soil Attributes S_a

This is called a regression tree. Pachepsky et al. (2001) used regression tree to predict sand and silt contents and water retention from terrain attributes (slope, curvature). One of the limitations in regression trees is the discrete predictions from each terminal node, which result in a lack of smoothness of the prediction surface. This can result in unrealistic representations of soil variability if the tree has a small number of terminal nodes (McKenzie and Ryan, 1999). An improvement to regression trees involves building multivariate linear models in each node (leaf). This type of model, which is analogous to using piecewise linear functions, has been implemented in the program Cubist (RuleQuest Research, 2000). This is used by Henderson et al. (2005) for mapping soil properties throughout Australia.

37.3.3.4.2 Prediction of Soil Classes S_c

This is called a decision tree or a classification tree. The binary decision tree algorithm uses a binary split that has exactly two branches at each internal node. There are different decision tree methods. The most commonly used is CART (Breiman et al., 1984). Lagacherie and Holmes (1997) discussed the application of CART for soil classification and its sensitivity to error. Another popular algorithm is C4.5 (Quinlan, 1992) and its later version See5 (RuleQuest Research, 2000). Bui and Moran (2003) utilized this program for mapping soil classes across the Murray–Darling Basin in eastern Australia. Moran and Bui (2002) refined the analysis of Bui et al. (1999) by using a "boosted" tree to reduce the classification error.

37.3.3.5 Neural Networks

Neural networks attempt to build a mathematical model that supposedly works in an analogous way to the human brain. Neural networks have a system of many elements or "neurons" interconnected by communication channels or "connectors," which usually carry numeric data, encoded by a variety of means, and organized into layers. Neural networks can perform a particular function when certain values are assigned to the connections or "weights" between elements. To describe a system, there is no assumed structure of the model, instead the networks are adjusted or "trained" so that a particular input leads to a specific target output. The mathematical model of a neural network comprises of a set of simple functions linked together by weights. The network consists of a set of input units, output units, and hidden units, which link the inputs to outputs. The hidden units extract useful information from inputs and use them to predict the outputs (Hastie et al., 2009).

Neural networks are now widely described in the soil science literature, mainly for predicting soil attributes. The application of neural networks as pedotransfer functions for predicting soil hydraulic properties is the most common.

37.3.3.5.1 Prediction of Continuous Soil Attributes S_a

The practice of predicting soil hydraulic properties in the form of pedotransfer functions can be found in many studies such as Minasny and McBratney (2002). Chang and Islam (2000) predict soil texture from multitemporal remotely sensed brightness temperature and soil moisture maps. Minasny et al. (2006) used a modified form of neural networks for mapping the parameters of a negative exponential depth function.

37.3.3.5.2 Prediction of Soil Classes S_c

Neural networks can be used to predict the probability of classes using multilogit transformation of the output. Another type of network is called self-organising maps (SOM, in this case, *not* soil organic matter) (Kohonen, 1982). Kohonen's network is an unsupervised classification splitting input space into patches with corresponding classes. It has the additional feature that the centers are arranged in a low-dimensional structure (usually a string, or a square grid), such that nearby points in the topological structure (the string or grid) map to nearby points in the attribute space.

Zhu (2000) used neural networks to predict the probability of soil classes from soil environmental factors. Fidêncio et al. (2001) applied two types of neural networks (radial basis function networks and

SOMs) to classify soil samples from different geographical regions in Sao Paulo, Brazil by means of their near-infrared (diffuse reflectance) spectra. Behrens et al. (2005) used neural networks to predict soil classes based on existing soil maps. The predictors are terrain attributes, geologic–petrographic units, and land use.

37.3.3.6 Fuzzy Systems

Zadeh (1965) defined a fuzzy set as "a class of objects with a continuum of grades of membership." Such a set is characterized by a membership (characteristic) function that assigns to each object a grade of membership ranging between 0 and 1. In classical Boolean logic, each individual, or site, either belongs to a class (membership = 1) or does not belong to a class (membership = 0). In Fuzzy logic, each individual, or location, is assigned a value between 0 and 1 that expresses the relative degree to which it belongs to a class. The degree of belonging to a given class (range 0–1) is assessed by comparing the properties that define the central concept for a class to the properties exhibited by any individual, or location, that one wishes to classify.

In the context of digital soil mapping, fuzzy systems represent one approach to assigning an estimate of the likelihood of a particular soil class or soil property value occurring at any given location under a given set of environmental conditions. Typically, the environmental conditions are represented by a series of covariates or predictor variables that exhaustively cover the spatial extent of an area for which predictions are required. The fuzzy likelihood that a given soil class or soil property value will occur at any point, and under any particular set of conditions, has been estimated using several quite different approaches. These approaches can be broadly characterized as unsupervised, supervised, and knowledge based (Hengl and MacMillan, 2009).

Unsupervised approaches typically do not have an a priori set of target classes defined and do not use spatially located reference locations to establish relationships between observed classes and values of the covariate predictor data sets. For example, Irvin et al. (1997) used a fuzzy *k*-means unsupervised approach to derive groupings of fuzzy soil–landform classes based solely on consideration of the input data values without reference to any existing classification. This approach used iterative processes to determine class means by minimizing distances in multidimensional attribute space. The resulting continuous classification created "partial" class memberships for each data point with membership values ranging from 0 to 1.

In situations in which the optimum number of classes to be identified, and the conditions or criteria that define the central concepts of each class, are not known a priori, statistical ordination techniques can be applied to extract class numbers and definitions. Fuzzy *k*-means or fuzzy *c*-means has been used extensively in soil science and DSM to identify optimum class numbers and central concepts and to then determine the fuzzy degree of membership of unclassified individuals or locations to the central concepts of each of the statistically defined classes (McBratney and De Gruijter, 1992; Odeh et al., 1992; De Gruijter et al., 1997; McBratney and Odeh, 1997; Burrough et al., 2000; Carré and Girard, 2002; Zhu, 2006). Detailed descriptions of the equations used in Fuzzy *k*-means, and the logic behind them, can be found in Odeh et al. (1992), McBratney and Odeh (1997), and Zhu (2006).

In digital soil mapping, most applications of fuzzy *k*-means classification have adopted an approach in which environmental covariates (e.g., slope, aspect, curvatures, climate variables, or vegetation cover) were used to define the central concepts of classes of soil of interest.

Supervised approaches all start out with a defined list of a priori classes that a user wants to predict and they all make use of spatially located reference data to establish the fuzzy membership functions that relate values of predictor variables to the corresponding likelihood that a particular soil class or property value will occur. These approaches all represent a form of data mining in which instances of known classes at known locations are used to identify values of predictor variables that are associated with the presence of a given class or property value. The training data can be drawn from a variety of different sources, including preexisting soil maps, preexisting (legacy) point observations or sample sites, newly collected, geolocated field observations or sample data or even points or areas identified interactively, on-screen, by a knowledgeable expert as being likely to belong to a particular class or to have a particular property value. A key requirement for successful use of supervised approaches is that there must be instances in the training data of all classes that exist in an area and that a user wants to predict. Additionally, the training data should cover, or represent, the full range of values exhibited by each and everyone of the covariates used to predict the fuzzy class memberships. A Latin hypercube sampling (LHS) procedure (Minasny and McBratney, 2006) can be used to analyze the feature space of the covariates to establish whether the instances in the training data represent the full range of covariate values in the feature space. If the training data do not fully cover the feature space, then there will be confusion as to which classes or property values are most likely to occur at locations in the feature space where there are no instances of training data for a particular range of covariate values.

Several different approaches have been described for collecting and analyzing training data to establish fuzzy membership functions for soil classes or properties. Some involve identifying multiple instances of each class of interest within an area of interest. Each instance, or location, is treated as a representative profile for a soil class of interest, and each unclassified location is compared to each instance of each class to identify the instance to which it is most similar (Zhu et al., 1996; Zhu, 2000). In a variation of this approach, Shi et al. (2004, 2005, 2008) treated individual locations are cases and assigned different weights to cases such that cases closer to an unclassified location carried a greater weight than cases farther away. This case-based reasoning (CBR) permitted instances of a class to influence the classification of unclassified locations that were located near to them while not exerting much influence on classification of locations that were further away.

37.3.3.7 Other Methods

Ballabio (2009) used support vector machine (SVM) algorithm for mapping soil organic carbon in mountainous regions in Italy.

SVM is a set of supervised learning methods used for classification and regression, and its algorithm aims to match model complexity to data complexity. SVM performs classification by constructing a nonlinear *n*-dimensional hyperplane that optimally separates the data into two categories. This is done by constructing a linear boundary in a large, transformed space of the feature space. Support vector regression is a form of SVM that is applied to regression problems.

Genetic algorithms (GAs) (Goldberg, 1989) are randomized search and optimization techniques guided by the principles of biological evolution and natural genetics. They have been used mainly in optimization of large multidimensional problems. Pal et al. (1998) developed a GA-classifier and applied it to satellite imagery (Pal et al., 2001). It attempts to approximate the class boundaries of a data set with a fixed number of hyperplanes in such a manner that the associated misclassification of data points is minimized. Nelson and Odeh (2009) explored the Genetic Algorithm for Rule-set Production (GARP) (Stockwell and Noble (1992). GARP was developed to model the habitat distribution of plant and animal species using locations of known species presence and environmental variables. The algorithm has stochastic elements that produce a population of rules prior to iterative use of the best rules in a given generation to develop the next generation until some convergence criteria are met and a solution given. GARP is noteworthy in that it was developed specifically to utilize legacy data. However, Nelson and Odeh's results showed that GARP did not perform as well as decision tree algorithm, implying the need to improve the algorithm for its full potential to be realized for digitally mapping soil classes.

37.3.3.8 Strengthening Models: Bagging, Boosting

There has recently been empirical evidence that the accuracy of *f*() prediction can be enhanced by generating multiple models and aggregating them to produce an estimate. There are two widely used approaches for producing and using several models that are applicable to a wide variety of statistical learning methods. Bootstrap aggregating or bagging (Breiman, 1996) and boosting (Freund and Schapire, 1997) manipulate the training data in order to generate different models. These methods arise more naturally in the supervised classification problem, but they can be extended to generic regression.

Bootstrap methods (Efron and Tibshirani, 1993) assess the accuracy of a prediction by sampling the training data with replacement. Suppose the training data are composed of predictors *Q* and response *S* of size *N*, we draw *B* data sets each of size *N* of the training data by sampling with replacement. For each of the bootstrap data set Z^b, $b = 1, 2, …, B$, we fit model $\hat{f}^b(q)$. The bagging estimate is calculated as

$$\hat{f}(q) = \frac{1}{B} \sum_{b=1}^{B} \hat{f}^b(q). \tag{37.13}$$

The bagging method is the basis of the random forests algorithm.

Boosting combines the outputs of many "weak" models to produce a powerful "committee." Boosting uses all the data at each repetition, but maintains a weight for each instance in the training set that reflects its importance. Adjusting the weights causes the model to focus on different data and, hence, leads to different models. The multiple models are then aggregated by voting to form a composite model. In bagging, each component model has the same vote, while boosting assigns different voting strengths to component classifiers on the basis of their accuracy. Moran and Bui (2002) used boosting to improve their digital soil map of the Murray–Darling basin. Henderson et al. (2005) described how fitting multiple trees through boosting and bagging permitted tree averaging, which could lead to potential improvements in the predictive power of decision trees.

Grimm et al. (2008) described random forest (RF) as an implementation of randomized classification and regression trees in which numerous trees are generated within the algorithm and finally aggregated to give one single prediction (Hastie et al., 2009). Random forests combine the tree predictors such that each tree depends on the values of a random vector sampled independently and with the same distribution for all trees in the forest. It has been used successfully for mapping soil carbon (Grimm et al., 2008). The model can handle lots of inputs, has a high accuracy, and apparently does not overfit the data. This is achieved by using different subsets of the training data (with bootstrap) and using different subsets of the predictors for training the tree (determined randomly). Thus, only patterns that are present in the data would be detected consistently by a majority of the trees. However, this claim is not always true. Hastie et al. (2009) showed that when the number of variables is large but the fraction of relevant variables for prediction is small, random forests are likely to perform poorly and random forests can certainly overfit the data; the average of fully grown trees can result in a model that is too rich and incur unnecessary variance.

37.3.3.9 Expert (Knowledge-Based) Systems

Expert systems (Dale et al., 1989) are ways of harvesting and engineering knowledge. The terms expert system and knowledge-based system have been used both interchangeably and for quite fundamentally different approaches. Zhu (2008) observed that knowledge-based approaches used in digital soil mapping have extracted and codified knowledge in three main ways, these being as follows:

- Extraction of knowledge from existing documents, legends, and keys
- Extraction of tacit empirical knowledge from human domain experts
- Extraction of knowledge from spatial data sets via data mining

Knowledge already formalized and codified in documents, legends, and keys may simply require implementation as either Boolean or Fuzzy rules and not require any specific extraction process. Empirical knowledge about likely relationships between classes of interest and formative environmental conditions can be extracted by asking local experts to describe and quantify their heuristic, and mostly tacit, domain knowledge through

structured interview and evaluation sessions (Zhu et al., 1996; Zhu, 2008). Extraction of knowledge via application of statistically based data mining techniques works by comparing the spatial co-occurrence of known examples of a particular class or entity with the spatial pattern exhibited by sets of covariates that are considered likely to possess some predictive relationship with the class or entity of interest. Interestingly, the widely used SoLIM (Zhu, 1997, 2008) and SIE (Shi et al., 2004, 2008) fuzzy inference systems have both utilized all three approaches to extract expert knowledge.

Let us first consider those expert systems that make use of some form of data mining technique. Data mining methods require two main inputs. First, they require evidence in the form of known observations of the classes or values of interest at known locations. These provide the training data. Training data may exist in either point or map form or both. Second, they require data sets of explanatory variables that are spatially referenced and cover entire areas of interest exhaustively. These explanatory data sets provide the means of developing and then extrapolating predictive relationships from point (or localized map) observations to entire areas of interest. Data mining can be considered as a form of supervised classification as described elsewhere in this chapter.

Decision trees, or classification trees (see Section 37.3.3.4), have emerged as a favored data mining approach in digital soil mapping. Another data mining method that has found some use in digital soil mapping is Bayesian Analysis of Evidence (Skidmore et al., 1991). Cook et al. (1996a) and Corner et al. (1997) developed and applied the custom software program *Expector* to capture and apply human heuristic beliefs in a structured belief system. Mayr et al. (2008) used commercial Bayesian analysis of evidence software, *Netica* by Norsys, to extract rules for classifying soil types by extracting knowledge from analysis of spatially referenced auger bore data and existing soil maps.

Bui (2004) observed that knowledge engineering is the study of expert systems and how experts build mental models. She argued that soil maps and their legends are representations of structured knowledge, namely, the soil surveyor's mental soil–landscape model. Soil map unit descriptions describe, in words, the soil–landscape relationships. For example, in a narrative legend, a soil toposequence can be described as a function of relative elevation/slope position, slope length and slope gradient, and curvature. Sometimes, the soil–landscape model for each map unit is represented as a 2D cross section or 3D block diagram. Soil map unit descriptions and block diagrams are usually the only way the soil surveyors' mental models are transmitted to others. This soil–landscape model has been described by Hudson (1992) as the operative paradigm for soil survey. Bui (2004) and Wielemaker et al. (2001) suggested methodological frameworks to formalize the landscape knowledge of the soil surveyor by structuring terrain objects in a nested hierarchy followed by inference and formalization of knowledge rules.

Knowledge-based expert systems have been characterized as consisting of two main components, these being a "knowledge base" and an "inference engine" (Skidmore, 1989). Zhu et al. (1996) described knowledge-based systems as being organized on three levels of data, knowledge base, and inference engine. Data refer to information on environmental conditions of an area such as elevation, slope, and aspect. The knowledge base contains the declarative knowledge about a particular problem being solved. In the case of predictive soil mapping, the knowledge base contains information about the relationships between the spatial distribution of soils in an area and the environmental factors that are believed, or known, to influence this distribution. The inference engine applies the knowledge to the data to produce predictions or results. It controls when and how the specific problem solution knowledge is used. A particular concern of an inference engine is often the order, or sequence, in which a particular piece of information (or a rule) is processed (Skidmore, 1989).

Shi et al. (2008) recognized several useful distinctions regarding knowledge used in devising and applying fuzzy logic rules. First, they distinguished between *global knowledge* and *local knowledge*. Global knowledge applies with equal validity across an entire area of interest whereas local knowledge is applicable only within certain restricted extents. Second, they distinguished between knowledge based on understanding of relationships between classes of interest and values of environmental variables in *parameter space* and knowledge based on the existence of known classes or conditions in particular locations in *geographical space*. They differentiated global rule-based reasoning (RBR), capable of handling global knowledge in parameter space, from global and local CBR, capable of handling global versus local knowledge in geographical space. CBR is used when local experts can identify locations at which specific classes of interest are known to occur and can state whether these classes always occur in these same settings throughout an area or only occur in these settings within a restricted geographical extent. RBR is used when local experts can identify the environmental conditions, as defined by available covariates, under which conceptual classes of interest are known to occur in parameter space.

Shi et al. (2008) provide an excellent description of eight main steps that are involved in devising, applying, evaluating, refining, and then finalizing knowledge-based rules to predict the spatial pattern of soil classes using the soil inference engine (SIE). They noted that MacMillan et al. (2007) independently, but not surprisingly, employed a procedure that was almost identical to theirs. The eight steps described by Shi et al. (2008) are as follows:

1. The soil scientist provides the global knowledge, including names of the soils he/she expects to see in the mapping area and descriptions of the environmental conditions of these soils. The environmental conditions depicted by environmental values are formalized into Fuzzy rules and saved into rule bases; those represented by geographical locations are formalized into cases and saved into global case bases.
2. The soil scientist or a GIS specialist prepares data layers for characterizing the environmental conditions. The data layers may cover terrain attributes, geology, vegetation, climate, and other features. These data layers are stored in a GIS database.

3. SIE performs RBR or global CBR, using the global knowledge and the GIS database, to generate maps of the general pattern of soil distribution in the mapping area.
4. The soil scientist verifies the draft maps from (3). If he/she is satisfied with the maps, the mapping is done. Otherwise, he/she may go back to (1) to adjust the rules or global cases, or go to (5) to fine-tune the draft maps.
5. The soil scientist provides the local knowledge, in the form of cases, to address local exceptions. The cases are saved in local case bases.
6. SIE performs local CBR using the local knowledge and the GIS database.
7. The soil scientist verifies the maps from (6). He/she can adjust the cases and run local CBR again. He/she repeats this process until he/she is satisfied with the result.
8. The soil scientist uses SIE and other GIS tools to integrate the results from (3) and (6) to generate the final maps.

The development of the SoLIM inference model (Zhu and Band, 1994; Zhu, 2006, 2008) through time provides a revealing example of trends in how fuzzy knowledge of soil–landscape relationships has been captured and applied. Early implementations of SoLIM were mostly based on using interviews to capture the tacit knowledge of local experts. However, they often did not take into account the consideration of the cognitive aspects of knowledge formulation and required users to provide either exact forms for membership functions for each class to be defined or a very large set of typical cases or instances that could be used as exemplars in CBR (Qi et al., 2006). In a second stage of development, many SoLIM applications relied on acquisition of large numbers of user-selected spatially referenced instances or cases to supply the information required to define central concepts, and local exceptions, for representative or typical soil classes (Zhu, 2000; Shi et al., 2004, 2005). As SoLIM subsequently evolved and was increasingly applied for operational mapping of larger areas, the use of large volumes of geolocated field observations to serve as training data sets became increasingly more costly and less viable. More recent applications of SoLIM have notably adopted approaches that were based on rapidly identifying prototypes (Qi et al., 2006) or semantically defined central concepts (Liu and Zhu, 2009) by using expert tacit knowledge to define conceptual or mental models of central concepts of soil classes to be predicted. These semantically defined representative concepts not only require far less time and effort to produce than geolocated reference sites but they have also been shown (Qi et al., 2006; Liu and Zhu, 2009) to be more effective and to produce more accurate predictions of the spatial distribution of soil classes than earlier case-based approaches.

The equation for computing an estimate of any given soil property of interest is given by Zhu et al. (1997) as follows:

$$V_{i,j} = \frac{\sum_{k=1}^{n} \mathbf{S}_{i,j}^k V^k}{\sum_{k=1}^{n} \mathbf{S}_{i,j}^k}, \tag{37.14}$$

where
$V_{i,j}$ is the continuous soil property to be predicted
$S_{i,j}$ is the soil similarity value for the soil k at location i,j
V^k is the mean or representative value for the soil property of interest for soil k

While this approach produces estimates that are not quite as accurate or reliable as those produced by other, more data intensive methods such as regression-kriging or regression trees, it is an attractive option for areas that lack extensive databases of geolocated point information on soil properties. In these circumstances, all that is required is a single representative value for each soil property of interest, for each depth or horizon of each soil class of interest and an ability to develop fuzzy knowledge-based rules about which environmental factors influence the development and occurrence of the soil classes of interest.

37.3.3.10 Unsupervised Classification

In the previous sections, when we were discussing classes we were considering "supervised classification." This is also known as allocation or identification. This is where we wish to produce prediction equations for placing soil existing soil classes, such as a particular categorical level in a national or international classification system. However, we may first wish to make new classes from the observed soil properties. This is known as unsupervised classification. Much of the early work on pedometrics, in the 1960s, focussed on this topic. The numerical classification methods that have been used quite extensively in soil science more recently are k-means and fuzzy k-means (Odeh et al., 1992; De Bruin and Stein, 1998; Triantafilis et al., 2001). See the section on fuzzy systems on the application of fuzzy k-means. There is also a semi-supervised classification considering classification in the presence of some labeled data (Pedrycz and Waletzky, 1997).

Unsupervised classification is an option for making digital soil class maps particularly where the national or international scheme does not project well onto the soil–landscape. However, once the new classes have been established at the soil observation locations, then one of the previous methods, inter alia discriminant analysis, multiple logistic regression, regression trees, needs to be applied to fit equations and then make predictions from environmental covariates at the other locations where no soil properties have been observed.

Carré and Girard (2002) used a continuous method for horizon and profile classification called OSACA. This was based mainly on field soil morphological attributes. Carré and Jacobson (2009) further developed a program for quantitative grouping of soil layer descriptions into profile classes. The program calculates the taxonomic distances between observed profiles based on layer (horizon) characteristics. Characteristics can be either observed soil properties or layer class memberships. OSACA can allocate observed soil profiles to existing classes or create a new classification of the profiles. Their method is unique in that it models the taxonomic distance to each of the class centroids at

each observation site. Because these distances are continuous variables, multiple linear regression on environmental variables was used as the "supervised classification" step. One regression equation was developed for each class and the distances predicted at each site on their prediction raster.

37.3.4 Spatial Considerations

The older *corpt* approach has no intrinsic or formal spatial component other than the functions are predicted in a spatial context, that is, spatial position is not taken into consideration. This seems unwise for a mapping application. Spatialization can be introduced by considering spatial components of the environmental and soil variables (Section 37.3.4.1) and by perpending the spatial correlation structure of the residuals (Section 37.3.4.1), as was briefly discussed in Section 37.3.3.1.

37.3.4.1 Decomposition of *Q* Factors into Spatial Components

DSM studies have increasingly recognized the need to identify which scales of variation, which are operative and discernable in the predictor data layers (*Q*), are most strongly related to observed variation in a property or class of interest (Bui et al., 1999, 2006; Fisher et al., 2004, 2005; Smith et al., 2006; Arrell et al., 2007; Deng, 2007; Wu et al., 2008; Zhu, 2008). Several approaches have been used to investigate the spatial structure that may be operative in predictor data sets and to identify the ranges of distance over which this structure operates.

Bui et al. (2006) observed that a spatial hierarchy emerged from their decision tree analysis of predictive relationships between environmental covariates and soil properties over the entire extent of the continent of Australia. They undertook a very logical, but frequently neglected, interpretation of their results in terms of physical and biological processes that influence pedogenesis. They sought to interpret their results in terms of the degree to which different environmental covariates, operative at different scales, could be related to soil-forming processes that influenced the values of the soil property variables they were modeling. Their results indicated that the state factors of soil formation formed a hierarchy of interacting variables, with climate being the most important factor at a continental scale, but with different climatic variables dominate in different regions. Their results also showed that lithology was almost equally important in defining broadscale spatial patterns of soil properties and that shorter-range variability in soil properties appeared driven more by terrain variables. The message to be taken from this thoughtful and rigorous analysis is that different environmental covariates are likely to drive the significant processes of soil formation at different scales and over different distances. Individuals seeking to model the spatial distribution of soil properties ought to first systematically examine the variation in those properties at different scales and seek to identify the environmental covariates (and their scales) that are most closely associated with causing variation in soil property values at specific scales.

In this same context, there has been an increasing number of studies that investigated the effects of different DEM resolutions (Zhang and Montgomery, 1994; Thompson et al., 1997, 2001; Fisher et al., 2004, 2005; Kienzle, 2004; Arrell et al., 2007; Erskine et al., 2007; Seibert et al., 2007; Wu et al., 2008) and neighborhood (window) sizes (Schmidt et al., 2005; Smith et al., 2006; Behrens et al., 2007a, 2007b; Zhu, 2008) on the performance of models designed to predict soil properties or soil classes. Typically, such studies have been applied to smaller areas over which the regional climate and lithology could be assumed to hold constant, or to vary only slightly, relative to more significant variation associated with topography. When predicting individual soil properties, the approach has often been to fit regression models in which the soil property of interest is predicted using environmental covariates computed at different neighborhood sizes and/or grid resolutions. For example, Schmidt and Hewitt (2004) showed that the predictive value of profile curvature for estimating soil properties in a regression model varied with the scale (window size) for which profile curvature was calculated. Similarly, Smith et al. (2006) showed that there was a range of window sizes, which varied from landscape to landscape, which produced the most accurate maps of soil classes, and that finer resolution DEMs did not necessarily create more accurate maps. They observed that there was no apparent physical process-based significance behind using a fixed 3×3 neighborhood for computing terrain attributes. Instead, they concluded that it is much more important to match the terrain characteristics computed from the DEM using a specified neighborhood size, with the characteristics of the real world landscape. In a subsequent publication, Zhu (2008) observed that soil-forming processes operated at specific scales, and that spatial analysis should employ a neighborhood size comparable to the spatial scale of the process under consideration. He argued for use of joint distributions of processes and parameters with recognition of effective neighborhoods, defined in terms of the extent over which a process of interest operates. This spatial extent is comparable to the concept of grain size and, for many soil–landscape studies, is equivalent to the extent defined by a hillslope from crest to channel.

Other approaches that have been used to investigate the spatial structure of environmental covariates include factorial kriging analysis (Bourgault, 1994; Wen and Sinding-Larsen, 1997; Oliver et al., 2000) and wavelets (Zhu and Yang, 1998; Carvalho et al., 2001; Mendonça-Santos et al., 2006). Both of these methods decompose the separate variables into separate hierarchical spatial components of decreasing spatial resolution. The factorial kriging method assumes stationarity while the wavelet method does not. The factorial kriging method finds the scale of the components from the observations, whereas in wavelets the various scales are dictated by the size of the image, that is, the scales are increasing powers of 2 pixels.

The various components of *Q* could conceivably all be derived at different spatial scales and used as separate layers in the fitting of *s*. It is more than likely that the short spatial range components (e.g., the nugget component) might not relate to soil and

can be removed (see Smith et al., 2006). In a quite a different application Oliver et al. (2000) found that land use was related to a long-range spatial component in SPOT imagery and not to two shorter range components.

37.3.4.2 Structure in *e*: Generalized Least Squares and Geostatistics

It would be naïve to imagine that there is no spatial structure in *e*. If *e* has a spatial structure, then GLS or geostatistics can be applied. Why would *e* have a spatial structure? The answers could be as follows:

- *Scorpan* is incorrect.
- Attributes used to describe *scorpan* are inadequate.
- Interactions are misspecified.
- Form of *f*() is misspecified.
- Something intrinsic—such as spatial diffusion, interaction, or inhibition processes.

Variograms of the fitted parts of the soil spatial prediction functions for the various factors will be instructive in elaborating these possibilities.

37.3.4.2.1 Generalized Least Squares

In GLS (Cressie, 1993): $\mathbf{s} = \mathbf{Qb} + \mathbf{e}$; errors $\mathbf{e}$ belong to multivariate normal distribution with mean 0 and covariance matrix $\mathbf{V}$: $N(0, \mathbf{V})$. For spatial data, it can be further simplified assuming the error is homogenous with variance σ^2; thus, $\mathbf{V}$ can be replaced by $\sigma^2\mathbf{C}$, where $\mathbf{C}$ is the correlation matrix of the errors (Lark, 2000).

GLS has been used in soil science literature, for example, Samra et al. (1991) predicted tree growth from soil sodicity parameters with spatially correlated errors. Other examples include Aiken et al. (1991), Opsomer et al. (1999), and Vold et al. (1999). Lark (2000) provided the theory and example of using GLS for mapping soil organic matter content. Hengl et al. (2003) utilized GLS as a regression-kriging procedure for spatial prediction of soil properties in Croatia.

The drawback with this method is the heavy computation time when a large volume of data is involved, as the calculation time of semivariance and inverse of the correlation matrix $\mathbf{C}$ will increase (approximately cubically with sample size); nevertheless, Opsomer et al. (1999) showed some mathematical manipulation to avoid the inversion of the whole matrix. Pace and Barry (1997) developed a spatial autoregressive model, which utilized the sparse matrix technique to allow for quick computation for large spatial data. Another approach has been to choose classes of covariance functions for which kriging can be done exactly, even though the data set is massive (Cressie and Johannesson, 2008). In this approach, a multiresolution spatial process is constructed explicitly so that (simple) kriging can be computed extremely rapidly, with computational complexity linear in the size of the data.

37.3.4.2.2 Geostatistics: Scorpan Kriging

Here, we recognize that the spatial "trend" can be described by $f(s, c, o, r, p, a, n)$, and the residuals e modeled separately by variograms and kriging. The final prediction is the sum of $f()$ and e.

37.3.4.2.2.1 Scorpan: Universal Kriging Universal kriging allows incorporation of both deterministic and stochastic components in kriging:

$$S(\mathbf{x}) = \sum_{j=0}^{p} b_j q_j(\mathbf{x}) + e(\mathbf{x}) + \varepsilon, \tag{37.15}$$

where

the first term represents the nonstationary trend, which is modeled as a set of linear functions of the environmental variables $\mathbf{Q}$ with parameter vector $\mathbf{b}$

the second term is the stochastic component modeled by variogram

the third component ε is the error term that occurs below the level of spatial resolution or support of the covariates

Universal kriging can be solved by modifying the kriging system. However, the trend function is only limited to linear functions, and when the number of variables p is large, the matrix inversion to solve the system can consume heavy computation time.

Alternatively, the trend function can be modeled separately, where kriging is combined with regression (Ahmed and DeMarsily, 1987; Knotters et al., 1995). This method involves regression of the soil attributes as a function of predictor variables. This is followed by kriging of the regressed values, where the variance of the predicted (from the regression model) is used as the uncertainty of the modified kriging system. This is also known as kriging with uncertain data (Ahmed and DeMarsily, 1987). Odeh et al. (1994, 1995) defined regression-kriging where model $f()$ is used to describe the relationship between predictors and soil attributes:

$$S(\mathbf{x}) = f(\mathbf{Q}, \mathbf{x}) + e'(\mathbf{x}) + \varepsilon, \tag{37.16}$$

where

$f(\mathbf{Q}, \mathbf{x})$ is a function describing the structural component of S as a function of $\mathbf{Q}$ at $\mathbf{x}$

$e'(\mathbf{x})$ is the locally varying, spatially dependent residuals from $f(\mathbf{Q}, \mathbf{x})$

In regression-kriging, the soil property S at an unvisited site is first predicted by $f()$ and then followed by kriging of the residuals of the model.

As discussed at the end of Section 37.3.3.10, Carré and Girard (2002) used a continuous method for horizon and profile classification followed by multiple linear regression on environmental variables. One regression equation was developed for the taxonomic distance to each class centroid, and the taxonomic distances were predicted at each site of their prediction raster. The residual taxonomic distances to each class centroid were then spatially predicted onto the raster using ordinary kriging and added to the taxonomic distances from regression analysis. The summed taxonomic distances were then displayed and manipulated to make class maps. In this way, regression-kriging can be

used to make continuous or discrete soil class maps taking into account the spatial correlation structure of the residuals from the fitted classes at each data point.

37.3.4.2.2.2 Scorpan: Simple Kriging Because $f()$ is modeled under the assumption that e has zero mean, simple kriging can be applied to the residuals of the model. Simple kriging allows prediction of the spatially correlated residuals with known mean where the weights of the kriging equation do not need to sum to unity (Webster and Oliver, 1990).

37.3.4.2.2.3 Scorpan: Compositional Kriging So far, kriging has been used mainly to predict soil attributes, for prediction of soil classes incorporating predictor variables **Q**, a form of compositional kriging with external trend is proposed:

$$\Pr[S_c(\mathbf{x})] = f(\mathbf{Q}, \mathbf{x}) + e_c'(\mathbf{x}) + \varepsilon, \qquad (37.17)$$

where $\Pr[S_c(\mathbf{x})]$ is the probability of the soil at **x** that belongs to soil class c. The probability of the soil classes $c = 1, \ldots, K$ must sum to 1 and the residuals of the probability must sum to 0:

$$\sum_{c=1}^{K} \Pr[S_c] = 1, \qquad (37.18)$$

$$\sum_{c=1}^{K} e_c' = 0. \qquad (37.19)$$

Solution of this method will involve prediction of probability of occurrence of soil classes using a form of $f()$, such as logistic regression, and compositional kriging of their residuals (Walvoort and de Gruijter, 2001).

37.3.4.2.3 Geostatistics: Co-Kriging and Coregionalization Analysis

Another method is co-kriging. Any of the q layers can be a covariate in co-kriging. Indeed, many people have used this. The major problems with co-kriging have been twofold. First, the parameters of all the $[(q + 1)q]/2$ variograms and cross-variograms have to be estimated and the parameters have to obey a strict inequality (Wackernagel, 1987). Secondly, and more importantly, the co-kriging model really assumes linear relationships between the predictor and predicted variables. The use of categorical predictors and predicted variables is also difficult. Odeh et al.'s experience (Odeh et al., 1995) was that co-kriging did not perform as well as $S = f(r) + e$ (regression-kriging) and was more cumbersome to use. We prefer the *scorpan* model, but co-kriging should not be dismissed and the difficulties and restrictions will be overcome. It can be argued that co-kriging is a kind of GLM. Co-kriging can be used for soil attributes, and compositional (co-)kriging (De Gruijter et al., 1997; Walvoort and De Gruijter, 2001) can be used for indicators or probabilities of discrete soil classes or memberships of continuous ones.

37.3.4.2.3.1 Coregionalization Analysis Even if co-kriging is not done, coregionalization analysis (e.g., Lark and Papritz, 2003) is a very instructive way of studying the linear spatial relationships between soil and the predictor variables Q. This will indicate the spatial scales over which we might expect linear relationships to hold.

37.3.4.3 Other Spatial Methods

Bayesian maximum entropy (BME) was introduced by Christakos (1990, 2000). This approach allows the incorporation of a wide variety of hard and soft data in a spatial estimation context. The data sources may come in various forms, such as intervals of values, probability density functions (pdf), or physical laws (Christakos, 2000). Bogaert and D'Or (2002) used BME algorithm and a Monte Carlo procedure (BME/MC) to generate a map of particle-size distributions from a limited number of accurate measurements and a spatially exhaustive soil map. Compared with ordinary kriging (OK), this approach has the advantage of using soft information on a sound theoretical basis.

Brus et al. (2008) used BME to estimate the probabilities of occurrence of soil categories in the Netherlands. They used "hard" observations from 8,369 soil profile descriptions, and the soil map of the Netherlands 1:50,000 as "soft" information. They concluded that BME is a valuable method for spatial prediction and simulation of soil categories when the number of categories is rather small (say <10). For larger numbers of categories, the computational burden becomes prohibitive, and large samples are needed for calibration of the probability model.

37.3.5 Recent Studies

Although the *scorpan* model was formalized in 2003, various authors have fitted parts of it. McBratney et al. (2003) summarized the work of a large number of studies. Their analysis showed that soil attributes have been estimated more often (70% of studies) than soil classes (30% of studies). The key predictor factors are r (80% of studies) followed by s (35%), o and p (both 25%), n (20%), and c (5%) whereas a does not seem to have been used as a factor. The most common combination was r and s. Most studies used a DEM as the main source of ancillary data, followed by remotely sensed imagery and preexisting soil coverage.

Grunwald (2009) reviewed more recent studies in digital soil mapping during the period of 2007–2008. Of the 90 reviewed studies, 40% focused on predictions of basic soil properties such as texture, bulk density, structure, 31% on soil carbon, 24% on environmental quality assessment, 17% on hydrologic properties, 9% on soil degradation (salinity, acidity, and erosion), and 16% on mapping of soil taxonomic/ecological classes. In particular, mapping of soil organic carbon was prominently represented. In these recent studies, about 40% utilized proximal or remote sensors, and 23% of the studies used sensor data to complement analytical soil data, which are more costly and labor-intensive to derive. The sensors include visual and near-infrared, mid-infrared, and apparent electrical conductivity.

37.4 Sources of Data: The Seven Scorpan Factors

There are seven factors or sets of variables in the *scorpan* model, which makes it different from Jenny's model. The aim is to obtain information on all of these. It will be a matter of convenience (access to data sources) and scientific contention, which variables are used to represent the factors. Indeed, this is an area that has not been well enough studied. The creation of these digital maps of the input environmental variables representing the six factors in the *scorpan* model is seen as an integral part of the digital soil resource assessment approach and a very valuable, environmentally useful, by-product of the new approach. The layers can be used for other modeling purposes. Much of the earth science and ecological research of the last 20 years has been contributing toward the creation of these layers.

These digital surfaces themselves will be created using surface modeling procedures; regression-kriging or Laplacian smoothing splines or TINS. For D3 surveys, they should probably be produced on a 100 m raster with a block size of say 100 m × 100 m.

Figure 37.1 highlights the useful parts of the electromagnetic spectrum for obtaining information on soil and environmental variables through remote and proximal sensing. Matter emits electromagnetic radiation in different parts of the spectrum, and this radiation may be measured by different types of spectroscopy depending on the wavelength. This provides a basis for remote sensing of the properties of matter. A sensing system might measure the radiation emitted by an object after the object has itself been irradiated. Two examples of this are the optical remote sensing systems that measure the solar radiation reflected by an object and the synthetic aperture radar systems (SAR) that measure deliberately long-wave radiation backscattered by an object. Alternatively, it may be possible to measure radiation emitted by an object because of its temperature (emitted in thermal infrared frequencies) or because of radioactive decay (decay of uranium, thorium, and potassium isotopes is widely measured by "passive" gamma radiometry in geophysics). The electromagnetic radiation emitted from an object will therefore depend on its physicochemical properties, some of which are of direct interest in the study of soil (the temperature, mineralogy, organic content, physical structure, or the chlorophyll content of overlying vegetation).

37.4.1 "s" Factor

Remote and proximal active and passive sensing gives detailed information on the soil itself—these reflections or emissions or transmissions are intrinsic properties of the soil material and profile they may indicate other soil attributes like texture or mineralogy. This factor is likely to becoming increasingly important as technology advances.

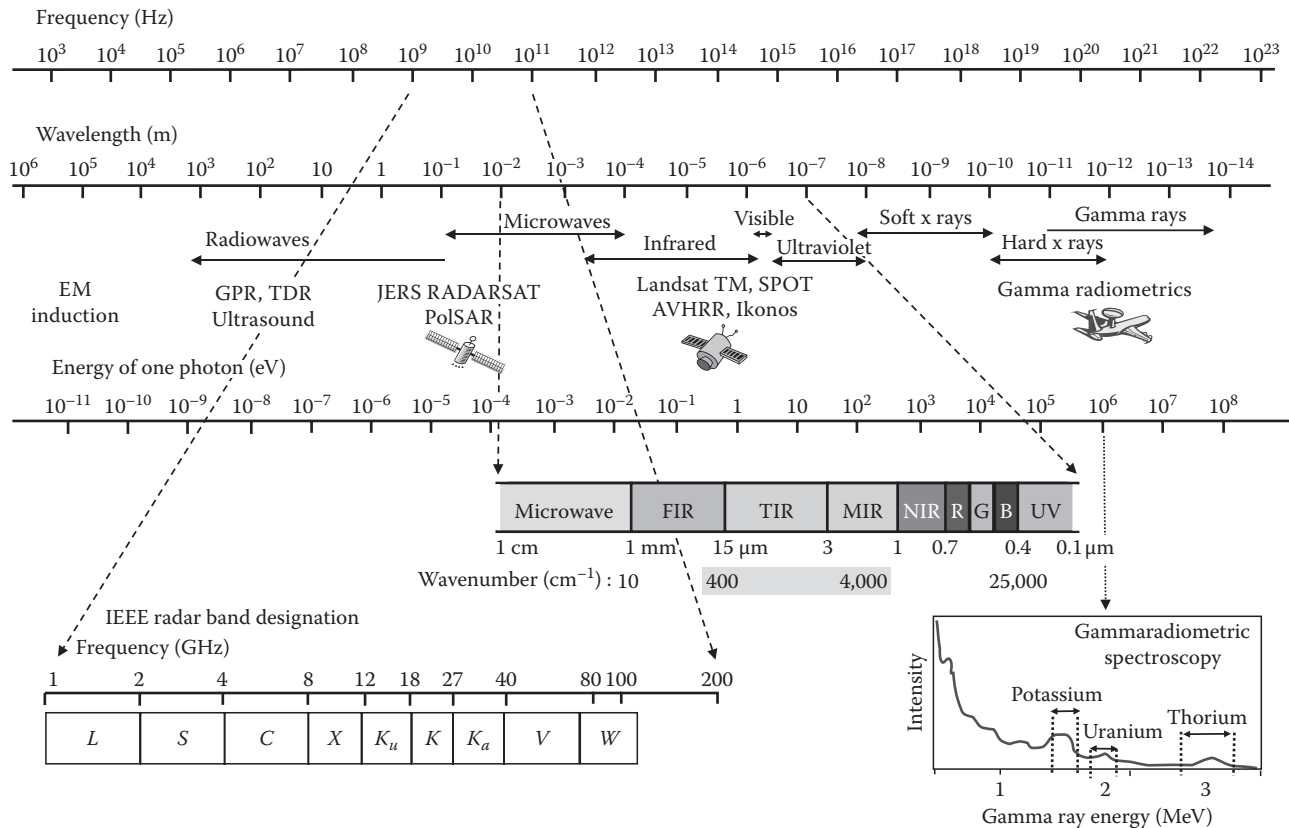

FIGURE 37.1   Electromagnetic spectrum showing various parts important for soil prediction.

37.4.1.1 Surface Multi- and Hyperreflectance

Hyperspectral sensors are those that measure a large amount of bands with spectral resolutions less than 20 nm (Palacios-Orueta and Ustin, 1998). In terms of mapping soil information, hyperspectral sensors have been found to be useful in mapping mineralogical features such as iron oxides (King et al., 1995), carbonates, and sulfates (Crowley, 1993). The amount of information generated by hyperspectral sensors poses computational problems in terms of extracting useful information in an efficient manner (see Section 37.3.3.1.2).

In a general way, the use of digital remotely sensing imagery for mapping soil has been problematic because vegetation cover obscures much of the soil response making it necessary to search for indirect evidence that may be visible at the surface (Campbell, 1987). Thus, remote sensing cannot be applied alone to soil studies (Lee et al., 1988). The use of proxies (such as topography, vegetation, drainage patterns) and field observations are important approaches for inferences about soil. In fact, mapping forest soil directly from remotely sensed data is difficult because of the complexity of environmental factors contributing to the spectral reflectance measured by a sensor. Nevertheless, forest soil was correctly mapped only where it was correlated with species or when vegetation is sparse or absent as a result of cultivation or drought (Post et al., 1994). The principal problems to soil delineation from such imagery, in addition to vegetation cover, are as follows:

- Soil moisture content can interfere with the spectral reflectance (specially in the infrared, thermal, and microwave regions (Obukhov and Orlov, 1964)
- Atmospheric effects (Cipra et al., 1980)
- Physical soil characteristics or disturbance patterns (Huette, 1988) and observation conditions (e.g., intensity and direction of illumination)

However, some research has been done in adjusting some of these drawbacks, by creating some indices with the main purpose of removing the effect of soil spectral influence (Huette, 1988) or even adjusting the images for vegetation interference, in combination with other information, and developing prediction models for improving soil mapping (Odeh and McBratney, 2000). In this way, Dobos et al. (2001) used satellite data complemented with DEM data, in order to correct the distortions caused by topographic variations of the landscape and provide additional data for soil–landscape modeling.

The presence of vegetation cover attenuates electromagnetic radiation at most wavelengths (Skidmore et al., 1997), and the reflectance at the soil surface does not always reflect soil variation at depth (Agbu et al., 1990). While infrared and visible sensors only measure surface characteristics, radar and gamma radiometry can provide spectral information beyond the vegetative cover and the soil surface.

37.4.1.2 Radar Attenuation

Information can be obtained by radar especially if there is a light-textured soil (low dielectric constant) over a heavier textured horizon (high dielectric) or a water table (very high dielectric),

and radar sensors can penetrate through soil to a depth that is equal to 10%–25% of their wavelength (Lascano et al., 1998). The longest wavelength radar sensor available from space platforms is 23.5 cm (L-band) on the JERS-1 satellite.

So far, we have only considered empirical methods where the multivariate prediction methods have been used to incorporate the remotely sensed imagery into prediction models. In the case of SAR, the backscattering signal is largely dependent on the dielectric properties of the media that is reflecting the signal, in the case of soil this is the volumetric moisture content (Moran et al., 1997). Therefore, physical models based on the theory of the diffraction of electromagnetic waves have been developed, an example being the integral equation model (IEM) (Fung et al., 1992). The model calculates a backscattering coefficient that is based on the following:

- Radar sensor configuration, for example, observation frequency, polarization, and incidence angle
- Surface characteristics, for example, roughness and dielectric properties

The model was adapted successfully to predicting soil moisture from bare soil surfaces by Altese et al. (1996). The presence of vegetation complicates matters, and it is currently too difficult to create models describing the interaction between soil–vegetation layers and microwaves in real world applications. Therefore, in the presence of vegetation, empirical approaches are required (e.g., Dobson and Ulaby, 1986; Wood et al., 1993).

37.4.1.3 Electrical Conductivity

Soil bulk electrical conductivity (or its reciprocal soil electric resistivity) reflects a combination of soil mineralogy, salts, moisture, and texture; hence, it is a good compound measure of soil. Two commonly used kinds of instruments are electromagnetic induction (EMI) and electrical conductivity/resistivity based on rolling electrodes (ECRE). The most widely used instruments for soil studies are the EMI devices from Geonics in Canada and two types of ECRE devices, a U.S. design (Lund et al., 1999) and a French one (Tabbagh et al., 2000). These instruments have been used extensively in precision agriculture for mapping soil types and properties (such as Bishop and McBratney, 2001; Sudduth et al., 2001; Anderson-Cook et al., 2002). Such proximal sensing offers the possibility of producing high-resolution maps of soil properties (D1 surveys of Table 37.1). Regression equations have been developed to predict moisture content, topsoil thickness, and clay content. EMI instruments can be placed in airborne platforms for catchment and regional mapping.

37.4.1.4 Gamma Radiometrics

Gamma-ray spectrometry (GRS) provides a direct measurement of natural gamma radiation from the top 30–45 cm of the soil (Bierwirth, 1996). A gamma-ray spectrometer is designed to detect the gamma rays associated with radioactive elements and to accurately sort the detected gamma rays by the respective energies (Grasty et al., 1991). Airborne radiometrics survey measures the radiation naturally emitted from the earth surface,

using gamma emitters like ^{40}K and daughter radionuclides of ^{238}U and ^{232}Th. K is a major constituent of most rocks and is the predominant alteration element in most mineral deposits. Uranium and thorium are present in trace amounts, as mobile and immobile elements, respectively. As the concentration of these radioelements varies between different rock types, we can use the information provided by a gamma-ray spectrometer to map rocks. Airborne methods (air gamma-ray spectrometer [AGRS]) provide valuable, systematic coverage of large areas, by providing information about the distribution of K, U, and Th that is directly interpretable in terms of surface geology. Nevertheless, AGRS is a surface technique only—interpretation requires an understanding of the nature of the surficial materials and their relationship to bedrock geology.

Although this technique has been employed for geological and mineral resource mapping for over 20 years, it has just become an interesting tool in soil science for detecting spatial variation of soil-forming materials (the *p* factor). It can also be considered as a direct, albeit compound, measure of the mineralogical and textural composition of the soil itself (*s*). Gamma-radiation data are usually provided in three channels—corresponding to spectral windows for K, U, and Th radiation. The apparent K concentration is likely to be most easily interpreted by pedologists. The value of gamma-radiometric data is increasing with the knowledge of their relation with soil-forming materials and when considered jointly with other information such as terrain models or aerial photography (Cook et al., 1996b) has become an important source of data for digital soil mapping. This technique has also been applied to estimate variation in surface soil moisture content (Carrol, 1981).

Rawlins et al. (2009) used airborne radiometric data and digital elevation data as covariates to map SOC distribution from an intensive survey in Northern Ireland. Radiometric data (K-band) and, to a lesser extent, altitude are shown to increase the precision of SOC predictions when they are included in linear mixed models of SOC variation. Division of the soil in Northern Ireland into three classes (mineral, organo-mineral, and peat) leads to a further increase in the precision of SOC predictions.

37.4.1.5 Existing Soil Class or Property Maps or Expert Knowledge

An existing soil map for parts of an area can be used to build a prediction model, or an experienced surveyor's expertise can be used to make simple rules that can be applied to a DEM, etc. These soil layers should be used as part of the information to build the new model—they should not really be the model itself. This is arguable, and there is further discussion in Section 37.5.12.

37.4.2 *"c"* Factor

Climate could be represented by mean annual temperature (*T*) and mean annual rainfall (*P*) and perhaps some measure of potential evapotranspiration (*E*). In the old literature, *P/E* was used to separate pedalfers from pedocals. A *P/E* ≪ 1 would imply semiarid conditions and precipitation of carbonates at depth.

Climate surfaces can be produced from meteorological stations interpolated by Laplacian smoothing splines (Hutchinson, 1998a, 1998b). This has been implemented in a program called ANUCLIM. The climate variables used are monthly mean values for minimum temperature, maximum temperature, precipitation, solar radiation, evaporation, and others. The climate surfaces can be used to generate secondary information, for example, bioclimatic parameters such as mean temperature of warmest period, precipitation of driest quarter, etc., which are useful in determining the climatic envelope for plant and animal species.

Published work suggests that remote sensing analysis can be used for estimating and mapping air temperature, soil moisture, and atmospheric humidity at regional to global scales. Air temperature can be inferred from normalized difference vegetation index (NDVI) data from the NOAA advanced very high-resolution radiometer (AVHRR). Several studies have shown that the surface albedo can be estimated using remote sensing data (i.e., Brest and Goward, 1987), and that net radiation can be calculated with sufficient accuracy (Kustas and Norman, 1996; Boegh et al., 2002).

37.4.2.1 Temperature

Surface temperature can be derived from remote sensing such as AVHRR, geostationary orbiting earth satellite (GOES) (Diak et al., 1998), and TIROS operational vertical sounder (TOVS) (Susskind et al., 1997). The TOVS has two sensors: the high-resolution infrared sounder and the brightness temperatures of the microwave sounding unit. These data can provide estimates of daily air temperature, humidity profiles, and surface temperature (Susskind et al., 1997).

Goetz et al. (1995) compared surface temperature derived from a multispectral radiometer (MMR) mounted on a helicopter (resolution ~5 m pixel), a C-130-mounted thematic mapper simulator (TMS) (~20 m pixel), and the Landsat 5 thematic mapper (120 m pixel). Differences between atmospherically corrected radiative temperatures and near-surface measurements ranged from less than 1°C to more than 8°C. Corrected temperatures from helicopter-MMR and TMS were in general agreement with near-surface infrared radiative, thermometer measurements collected from automated meteorological stations while the Landsat 5 TM systematically overestimated surface temperature.

37.4.2.2 Precipitation

Spatially distributed precipitation estimates can be derived from rainfall gauge measurements (interpolated using splines or other techniques) or by remote sensing. Records of gauge measurements of monthly precipitation are available throughout the entire twentieth century, while satellite estimates can provide monthly to hourly resolution since 1974. A review has been presented by New et al. (2001).

37.4.2.3 Evapotranspiration

Li and Lyons (2002) estimated regional evapotranspiration in central Australia, using limited routine meteorological data and the AVHRR data. Their model attempts to minimize the

difference between model-predicted surface temperature and satellite-derived temperature to adjust the estimated soil moisture. They suggested that radiometric surface temperature can be used to adjust simple water balance estimates of soil moisture providing a simple and effective means of estimating large-scale evapotranspiration in remote arid regions.

Boegh et al. (2002) used Landsat-TM data to estimate a composite evaluation of atmospheric resistance, surface resistance, and evapotranspiration. The input parameters were surface temperature, net radiation, soil heat flux, air temperature, and air humidity. The application of the technique in a remote sensing monitoring context was demonstrated for a Danish agricultural landscape containing crops at different stages of development.

37.4.2.4 Water Balance Components

The familiar water balance formulation is

$$P + I = \Delta S + E + T + R + D, \tag{37.20}$$

where

P represents precipitation
I represents irrigation
ΔS represents change in soil moisture
E represents evaporation
T represents transpiration
R represents surface runoff
D represents deep drainage

Precipitation and evapotranspiration can be estimated from remote sensing data. The most important component relating to soil itself is soil moisture, and much research has been focused on estimating spatially distributed soil moisture (see also Section 37.4.1.2). Jackson et al. (1996) gave an overview of remote sensing techniques for estimating soil moisture. Many studies have successfully demonstrated the use of infrared, passive, and active microwave sensors to estimate soil moisture (Hoeben and Troch, 2000). Microwave remote sensing of soil moisture is based on the soil's dielectric properties. The large difference between the dielectric properties of dry soil and moisture enables good calibration. The analysis is based on a model that simulates radar backscattering given known surface characteristics such as moisture and roughness. Passive microwave sensors have the advantage of less dependence on soil surface roughness. The main disadvantage with spaceborne sensors is that they produce coarse-resolution images. This problem is overcome in active microwave sensing through the use of SAR sensors (10–100 m). This has been used to monitor spatial and temporal soil moisture at catchment scale (10–1000 km^2) both in vegetated and nonvegetated areas (Lin et al., 1994; Su et al., 1997). Mancini et al. (1999) evaluated the use of multifrequency radar observations in the laboratory for estimating soil moisture.

Murphy et al. (2009) used a fine resolution digital elevation model to model soil moisture conditions in Alberta, Canada. They compared the compound topographic (wetness) index (CTI) with a new algorithm that produces a cartographic depth-to-water (DTW) index based on distance to surface water and slope. They found that their DTW model was closer to field-mapped conditions. All major wet areas and flow connectivity were reproduced and a threshold value of 1.5 m DTW accounted for 71% of the observed wet areas.

The soil moisture and ocean salinity (SMOS) satellite mission was launched in November 2009. It operates under the L-band (1.4 Ghz) and was designed to observe soil moisture over the Earth's landmasses and salinity over the oceans. A global soil moisture map with accuracy better than 0.04 m^3/m^3 can be produced every 3 days; however, the spatial resolution is very coarse (50 km or better).

37.4.3 *"o"* Factor

The "organisms" factor is a basic term encompassing biota composition or the flora and the fauna of specific region. Flora stands for vegetation description whereas the fauna means the animals, microorganisms, and even human activities. In pristine or newly developed environments, the "natural" vegetation class should represent some kind of equilibrium relation with soil type. In that case, the vegetation is an indicator of the underlying soil type. However, "natural" vegetation is quite uncommon to find since it has frequently been disturbed by human activities (generally called "land uses"). Vegetation and land uses, generally provided by land cover analysis, can then be either an indicator of the underlying soil type or a determinant of the soil type. After defining land use and vegetation, their source of data, their relationships with soil, as determinant or indicator, can be explained.

37.4.3.1 Land Use Information and Relationships with Soil

Three kinds of land uses are generally distinguished: settlements (cities, mines, industrial areas, etc.), agricultural activities (arable lands, pastures, plantation, etc.), and natural or seminatural areas (natural forests, natural grasslands, bare rocks, and water). This information is generally provided by remote sensing images providing access to land cover. While settlements are usually easy to distinguish from above, it is often difficult to punctually differentiate agricultural pastures from natural grasslands, bare soils of arable lands from bare rocks, and plantations, or harvested areas, from natural forests. To this end, historical ground inventories, long-term imageries, or time-series analysis of remotely sensed images should be included in the mapping process of land uses. In that sense, land use information can be crucial for assessing the "*a*" (or time/age) factors. Schulp and Veldkamp (2008) made an inventory of historical land use. They showed that coarse resolution (500 m) historical patterns can explain up to 75% of the soil organic matter variability, whereas actual land use only explains 2% of the variability. Moreover, the IPCC report (2006) provided increase or decrease coefficients of soil organic carbon stocks according to land use or land cover conversions. This information is then crucial at the global level.

37.4.3.2 Vegetation Definitions, Data, and Relationships with Soil

Vegetation information is one of the most used "scorpan" factors along with landform. It is usually obtained from intensive ground survey and/or from visible and infrared reflectance by remote sensing being enhanced more recently by microwave imagery (Clevers and van Leeuwen, 1996). It comprises biomass deriving from agricultural activities and from natural or semi-natural areas. Three kinds of components should be described: the type or species of vegetation, the intensity of vegetation or biomass quantity, and the area covered by vegetation usually called "vegetation coverage."

37.4.3.2.1 Vegetation Type or Vegetation Land Cover

The vegetation type is usually assessed by doing a classification of remote sensing multispectral imagery on the spectral signatures of the image pixels (Figure 37.2). Vegetation is mainly discriminated by wavelengths at 0.55 μm in the green region, at 0.67 μm in the red region, and at 0.87 μm in the NIR region (Bunnik, 1978). Classification can be supervised using ground measurements or unsupervised when applied directly on the pixels. For tree species, and for very fine resolution, when there is a priori knowledge of the species, it is possible to use airborne laser scanning (Lidar) for differentiating the trees according to their morphological attributes such as tree height, stem diameter, and crown radius (Ørka et al., 2009). Carré and Girard (2002) used information on spectral bands for assessing the spatial distribution of soil types using linear regression. Hansen et al. (2009) used multispectral data and topography for assessing soil–landscape units.

37.4.3.2.2 Vegetation Intensity or Biomass Quantity

According to vegetation species and its state of development, chlorophyll absorbs more or less solar energy. The absorbed or transformed energy that represents biomass production is usually modeled by combining different visible and near-infrared bands. The produced indices are then not only indicating vegetation types but also primary production. These indices are NDVI (Rouse et al., 1973), EVI (Waring et al., 2006), and FAPAR (Gobron et al., 2000).

Furthermore, concerning crops, the use of yield monitors on harvesting machines also provides a source of spatial biomass information (Stafford et al., 1996). Bishop and McBratney (2001) used yield-monitored wheat yield to aid in the prediction of soil clay content. Yield-monitored data are currently useful for D1 mapping (Table 37.1).

37.4.3.2.3 Vegetation Coverage or Area Covered by Vegetation

The area covered by vegetation, whatever the vegetation type, can be assessed using the indices explained before. This allows for usually discriminating bare soil from lands covered by vegetation and thus assess potential risks related to soil vulnerability like wind erosion (Skidmore, 2006). Many publications describe the role of vegetation on different soil processes, on the spatial distribution of soil at different scale, and for different time periods (months, year, and decade). It is then important to take this factor into account for digital soil mapping.

37.4.4 "r" Factor

Topography has long been recognized as one of the main soil-forming factors (Jenny, 1941). Milne (1935) introduced the concept of a catena to describe a predictable and recurring pattern of soils that occupied a topographic sequence along a hillslope from divide to channel to divide. Aandahl (1948) was the first to quantitatively relate landscape attributes to soil properties. Troeh (1964) fit a cylindrical parabola to contour lines to derive

FIGURE 37.2 Ultraviolet-infrared spectrum showing important parts for sensing vegetation indices.

slope and curvatures. These landform parameters were derived to correlate to soil drainage classes.

Almost all DSM studies reflect a recognition that changes in the value of soil properties or the classification of soils occur in response to environmental gradients and that many environmental gradients of interest are strongly related to elevation, moisture, and energy gradients that are defined and controlled by local and regional topography (Milne, 1935; Burrough et al., 2000; McKenzie et al., 2000).

The principal assumption underlying the soil–landform paradigm is that the distribution of soils in the landscape is predictable and that, at least at a local scale, this distribution is largely controlled by how topography influences the distribution and redistribution of moisture, energy, and materials in the landscape. Terrain derivatives computed from digital elevation data can provide useful measures for predicting and quantifying how topographic controls influence this distribution and redistribution. They therefore represent a primary source of explanatory variables for most efforts to implement automated predictive soil mapping. Many would argue that digital terrain modeling is the most useful and quantitatively developed factor for predicting soil attributes and soil classes, at least at a local (hillslope) scale (McKenzie et al., 2000).

Topography has increasingly come to be described and quantified by means of digital elevation models (DEMs). Initially, DEMs were produced by digitizing existing contour maps or by extracting spot elevations and stream-line data from traditional land surveys and then interpolating these contour or spot elevations to a regular grid (or using them to create a triangular irregular network or TIN). More recently, DEMs have been produced more rapidly, cheaply, and at a finer spatial resolution by means of automated stereo autocorrelation of stereo image pairs obtained from airborne or satellite sensors, by interpolation of dense ground point observations obtained from vehicle-mounted high-resolution GPS receivers, or from very fine resolution clouds of point elevation data obtained using airborne lasers (LiDAR) or synthetic aperture radar (IfSAR or InSAR). See Nelson et al. (2009) for a thorough review of DEM production methods and sources.

The use of elevation data in digital form involves quantitative parameterization of the surface model or the numerical description of continuous surface form (Pike, 1988; Wood, 1996). Pike et al. (2009) observed that geomorphometry is fundamentally concerned with the quantitative measurement and extraction of both land surface parameters (LSPs) and land surface objects (LSOs). An LSP is a descriptive measure of a surface attribute (e.g., slope, aspect, and wetness index), usually arrayed as a continuous field of values and usually organized as a raster image or map. An LSO is a discrete surface feature (e.g., a watershed line, cirque, alluvial fan, and drainage network) that is usually represented as a vector object defined by points, lines, or polygons (see also Deng, 2007).

Parameterization means to quantitatively measure continuous properties of a landscape that can be used to describe form (Wood, 1996). Geomorphometry involves quantification of form but can also include consideration of different measures of pattern, texture, and hydrological, gravitational, or spatial context, as well as the extraction of geomorphologic objects. A wide range of LSPs can be extracted from a DEM, such as altitude, slope, aspect, different curvatures, upslope contributing area, and compound topographic index (CTI). Similarly, DEMs can be processed to identify and delineate a wide range of discrete LSOs.

For discussion purposes, LSPs have frequently been grouped into primary and secondary topographic attributes (Moore et al., 1993; Wilson and Gallant, 2000). Primary attributes are measures of a single aspect of the land surface whose calculation does not require combination of two or more separately computed values. Primary attributes are often further differentiated into local attributes, such as slope, which are computed within a neighborhood window of fixed (but now increasingly of variable) dimensions and regional attributes, such as contributing area, whose calculation extent is not predetermined or fixed but varies according to conditions imposed by a particular set of land surface data. Secondary terrain attributes are any attributes (such as wetness index) whose values are computed using a combination of two or more primary attributes (Wilson and Gallant, 2000).

37.4.4.1 Primary Terrain Attributes

Primary attributes have been used successfully in numerous studies to predict different soil attributes and classes. Maintaining the above distinction of local versus regional primary attributes, we observe that local attributes mostly describe the height, orientation, and shape of the land surface at a point or, more correctly, within a region defined by a rectangular (or sometimes circular) window surrounding a point. The main primary local attributes are elevation, slope, aspect, and various measures of curvature.

Elevation in its raw form mainly influences regional and local climate through its effect on surface temperature and precipitation (Deng, 2007). Elevation has also been used in numerous DSM studies as a local indictor of relative slope position within restricted areas (Shi et al., 2004). Slope and aspect describe the orientation of the local land surface within a neighborhood window. Curvatures primarily describe the shape of the local land surface within the window.

Shary et al. (2002) highlighted the importance of recognizing that many terrain attributes are field specific, insofar as they are computed with reference to a particular vector field, such as the gravitational field. Slope, aspect, profile and plan curvature are all computed relative to the orientation of the normal to the gravity vector. When interpreting these measures, the implicit assumption is that the current orientation of the land surface reflects the conditions that existed over the period of time that a soil was formed. For example, a closed depression (nondraining) can change to an open depression (draining) if the land surface tilts at some point in time after the formation of the closed depression.

Evans (1972, 1998) provided an overview of primary terrain attributes in relation to their geomorphologic meaning. Slope is

frequently interpreted in terms of the amount of energy associated with a particular slope gradient that is available to drive soil-forming processes such as runoff, erosion, and deposition. Aspect, in combination with slope, is often interpreted in terms of exposure to incoming solar radiation, drying prevailing winds, or accumulation of snow or sediments in sheltered lee slopes. Curvature is generally interpreted in terms of how local shape affects surface runoff, erosion, and deposition. Areas that are convex in profile or plan are considered likely to shed water, to cause divergence of surface flow (in plan) and acceleration of surface flow (in profile), and to consequently be drier than normal sites. Areas that are concave in plan (across slope) are considered to favor convergence of surface flow and development of moister conditions. Areas that are concave in profile (downslope) are considered to favor deceleration of surface flow and deposition or accumulation of both moisture and sediments. Curvature also has often been interpreted as an indication of relative position on a hillslope (see Pennock et al., 1987). Areas that are convex in profile were interpreted as indicative of crests and shoulders while areas concave in profile were interpreted as indicating decelerating positions in toe slopes. Areas that are planar in profile have been associated with back slopes.

The majority of DSM studies appear to have preferred to make use of the most commonly computed local terrain attributes slope, aspect, profile curvature, and plan curvature computed using the most commonly available algorithms. Shary et al. (2002) described instabilities in the calculation of plan curvature and suggested that it not be used and instead replaced with its close equivalent of horizontal curvature. Many subsequent studies adopted the use of either horizontal or tangential curvature in preference to plan curvature to characterize curvature in the across slope direction (Schmidt et al., 2003; Schmidt and Hewitt, 2004).

Local terrain attributes are typically taken to provide an indication of the shape or orientation of the land surface only, that is, its form. However, the increasing trend to compute these variables over a range of grid resolutions and window dimensions produces information that can be interpreted to quantify characteristics of the land surface that describe texture, pattern, scale, and context. The magnitude and frequency of variation in these local terrain attributes within expanding neighborhood windows can provide useful measures of pattern and texture in the landscape. It can also help to establish the characteristic distances over which variation in these properties occurs. This can be interpreted as a measure of the size and scale of the landscape. Finally, multiple measures of slope, aspect, and particularly curvatures within expanding calculation windows can be interpreted in terms of the position or context of a grid cell in the landscape (e.g., a ridge in a pit located on a larger ridge) (Wood, 1996).

Many primary regional topographic attributes provide information about some aspect of topographic or hydrological position or context. The most commonly used primary regional attribute is upslope contributing area or drainage area also rescaled to compute specific catchment area (SCA). Calculation of this attribute involves tracing down flow directions and accumulating a sum for the area upslope of every cell that contributes drainage to each downslope cell. This calculation can involve using a single steepest flow direction algorithm (the so-called D8 algorithm) to assign all flow from each cell into its steepest downslope neighbor, or it can utilize one of several different algorithms that partition flow from each cell according to some estimate of the proportion of flow that might logically be expected to pass from a given cell into each of its neighbors of equal or lower elevation. This attribute provides a measure of relative position in the landscape within the context of simulated hydrological flow of surface water.

Many primary regional attributes represent efforts to capture the relative position in the landscape of a point or the amount of relief (and therefore potential energy) associated with the area upslope (or downslope) of a point with respect to some other significant reference point, such as a channel or a ridge. Measures of relative landform position have been reported that are based on calculations of the variation in elevation (Pike, 1988) or mean slope (Fels and Matson, 1996) within fixed windows of various dimensions. Wilson and Gallant (2000) identified a number of measures of variation in elevation within circular windows centered at a grid cell.

Skidmore (1990) introduced one of the first algorithms for computing a measure of relative slope position. It involved first classifying cells as either ridges (convex) or channels (concave), based on their local surface shape. An expanding search window centered on each grid cell was then used to determine the Euclidian distance from each cell to the closest ridge and channel cells. This approach has the potential disadvantage that the closest channel or ridge cell may not be the one to which a given cell is connected by a path of surface water flow (see Rennó et al., 2008). MacMillan et al. (2000a, 2000b) implemented an algorithm for computing a variety of different measures of absolute and relative landform position and relief that was based on tracing both upslope and downslope along simulated paths of surface flow to locate and measure the horizontal, flow length, and vertical distances to critical cells designated as belonging to pits, peaks, channels, or divides. This approach has been proposed or implemented by others as well (Bell et al., 1992; McSweeny et al., 1994; Bui and Moran, 2001). Interesting and useful alternate measures of relative position in the landscape have been described in terms of valley bottom index (Gallant and Dowling, 2002) and openness (Yokoyama et al., 2002). Relative landform position tends to be a key conceptual consideration in many human-devised systems of soil or landform mapping, and measures of landform position and context have increasingly come to be used as explanatory variables in digital soil mapping (Bell et al., 1992; Bui and Moran, 2001, 2003; Schmidt and Hewitt, 2004; Schmidt and Andrew, 2005; Schmidt et al., 2005).

See Wilson and Gallant (2000) for a review of primary and secondary topographic attributes including various measures of slope and area computed for cells upslope of a central cell that contribute flow into it (contributing area) and cells downslope of a given cell into which it contributes flow (dispersal area).

37.4.4.2 Secondary Terrain Attributes

Secondary terrain attributes are computed from the primary attributes. These have been described in detail by Wilson and Gallant (2000). These attributes usually combine two or more primary attributes to characterize the spatial variability of specific processes in the landscape. The most widely used is CTI or also called wetness index:

$$\text{CTI} = \ln\left(\frac{A_s}{\tan\beta}\right), \qquad (37.21)$$

where
A_s is the upslope area
β is the slope

Wilson and Gallant (2000) also provide routines for the calculation of erosion, solar radiation, and dynamic wetness indices.

Wilson and Gallant (2000) list and document a number of secondary topographic indices including three different versions of the wetness index or CTI, a stream power index (SPI), a sediment transport capacity (STC) index, a channel initiation (CI) index, and several radiation and temperature indices. All of these can prove useful in efforts to automatically classify landform-based terrain elements. The secondary topographic attribute that is most widely reported as being used in efforts to automatically classify landform entities is the wetness index or CTI (Beven and Kirkby, 1979; Moore et al., 1991a, 1991b, 1993; Wilson and Gallant, 2000).

37.4.4.3 Terrain or Landscape Classification

In contrast to the preceding discussion of continuous LSPs, landform classification locates and extracts identifiable LSOs from digital elevation data. These objects occur across a range of scales, and their recognition can involve varying degrees of subjectivity.

Within the context of digital soil mapping, there have been three main areas of application of landform classification. The first has been the identification of critical points, or surface-specific points (Peucker and Douglas, 1975), based largely on local surface shape. The second has been the identification and classification of areas of relatively homogeneous terrain conditions, referred to as landform elements, which are usually identified as components of a hillslope along a sequence from crest to channel. These landform elements are usually described as being occupied by a single soil series or a narrow range of similar soil series. The third application has involved recognition of regional landform patterns, which are typically described as being occupied by repeating combinations of different soils, such as soil associations or complexes. Each of these three major approaches is reviewed in brief as follows.

Recognition of critical points, or surface-specific points (Peucker and Douglas, 1975), based primarily on local surface shape has been a key component of automated landform classification since its inception. Pike et al. (2009) cite Cayley (1859)

as having been the first to identify and describe the conceptual importance of these points in describing landforms. Critical points and lines identify local maxima and minima in the landscape and help to establish horizontal and vertical scale and context for landform classification. Their identification is relatively objective and crisp but some ambiguity occurs when local surface shape is not pronounced enough to identify pits, peaks, channels, or ridges definitively. Ambiguity also exists with respect to the scale at which these objects are identified. Wood (1996) showed how extraction of these critical objects within multiple windows of expanding dimensions could result in classification of the same point as, for example, a pit within a peak within a pit. This multiresolution analysis approach has been increasingly recognized as a valuable way to assess context and form across multiple scales (Deng, 2007).

The surface-specific points and lines described above delineate a mesh, or framework, of hillslope entities bounded by ridge lines and course lines. The intersection of ridge lines and course lines delineates areas that represent individual hillslopes that run from local divides down to local channels. Pike et al. (2009) cite Maxwell (1870) as having been the first to observe that the area enclosed by these lines was part of both a *hill*, whose lines of slope run down from the same summit and a *dale*, whose slope lines run down to the same pit. These semantics emphasize the relationship of these points and lines to patterns of local surface water flow. Not surprisingly then, essentially the same points and lines can be extracted by computing networks of simulated surface water flow and extracting pits, peaks, channels and divides from the flow networks. This has been done by Band (1989a, 1989b, 1989c) who used pixel to pixel hydrological connectivity to define fundamental terrain units based on the intersection of complementary divide and channel networks. Hillslopes were defined as the areas between a channel segment and its associated drainage divide.

Identification of these pits, peaks, channels, and ridges plays a significant role in other aspects of landform analysis and classification. First, several useful LSPs, such as horizontal distance or change in elevation to a ridge or channel, need to first identify these significant points and lines in order to be computed. Second, these critical points and lines establish the context and boundaries within which subsequent efforts to identify and classify landform elements operate. Third, many of the reported approaches for classifying landform patterns make use of information on the scale and spacing of ridges and channels to establish measures of context and pattern used in classifying landform patterns.

A landform element is a subcomponent of a landform pattern. Landform elements may be conceptualized as consisting of portions of a landform pattern that are relatively homogeneous with respect to shape (profile and tangential curvature), steepness (gradient), orientation or exposure (aspect or solar radiation), moisture regime, and relative landform position (e.g., upper, mid, or lower). Speight (1990) recognized more than 70 types of landform elements and gave as examples cliffs, foot slopes, and valley flats. Dikau (1990) recognized simpler form units, or

form facets, nested within form patterns, that were described by inherent shape-based attributes such as curvature, gradient, and aspect. Dikau (1989) differentiated form elements with homogeneous plan and profile curvature from even more homogeneous form facets that had uniform gradient, aspect, and curvature.

The majority of applications of landform classification in digital soil mapping have represented efforts to identify and extract landform elements arranged in a topographic sequence along hillslopes from crest to channel (Park et al., 2001). These classifications were usually intended to build upon conceptual classifications of hillslopes into summits, shoulders, back slopes, foot slopes, and toe slopes as proposed by Ruhe (1960) or the 9 unit classification of hillslopes proposed by Dalrymple et al. (1968) and Conacher and Dalrymple (1977) or the 10 types of topographic landform positions described by Speight (1990).

Classification of landform patterns is generally more challenging than classification of landform elements along a single hillslope. Not surprisingly then, there have been fewer approaches described for automatically classifying landform patterns and fewer applications of landform pattern classification in digital soil mapping. Classification of landform patterns has mainly been used to establish domains, or regions, over which a particular recurring pattern of soils and terrain (e.g., a soil association) is observed to occur and within which a particular set of classification rules for a limited number of soil classes is thought likely to apply (Dobos et al., 2000, 2001; Bui and Moran, 2001, 2003; Henderson et al., 2005; Bui et al., 2006; MacMillan et al., 2007).

The de facto standard for classifying landform patterns is Dikau et al.'s (1991, 1995) computerized implementation of the manual system of landform classification proposed by Hammond. The method of Dikau et al. (1991, 1995) follows Hammond (1954, 1964) in recognizing, within a window of fixed dimensions, 4 classes of proportion of gentle slopes, 6 classes of relative relief, and 4 classes of profile type, which, when combined, lead to 22 possible landform subclasses (Brabyn, 1998). These are commonly regrouped into 24 landform classes and 5 major landform types of Plains, Tablelands, Plains with Hills or Mountains, Open Hills and Mountains, and Hills and Mountains (Bayramin, 2000).

Brabyn (1997, 1998) noted two problems with implementation of Dikau's methods. The first was a pattern of progressive zonation that developed in transition zones between areas of high and low relief. The second was that the methods classified areas with quite different macro landform into the same class. Guzzetti and Reichenbach (1994) also identified concerns with imprecise boundary locations and mixed classification and tried to address them by developing and applying a different approach that combined automated classification of DEM data with manual interpretation and digitizing of clear, sharp final boundaries.

There have been relatively few other approaches reported for classifying landform patterns from digital elevation data. Bui and Moran (2003) used the computed values of total distance from ridge to channel to produce a map of relief classes (<9, 9–30, 30–90, 90–300, and >300 m) to define physiographic regions that exhibited signature soil patterns. Similarly, MacMillan et al. (2007)

used the total relief computed for individual hillslopes to define classification domains of different relief within which fuzzy rules were used to classify ecological site types along toposequences from crest to channel.

Iwahashi and Pike (2007) proposed an alternative approach for classifying landform types at multiple scales that is very simple, efficient, and effective. This approach uses only three inputs of slope gradient, local convexity, and surface texture (feature frequency and spacing). The method is locally adaptive as it does not use fixed threshold values to distinguish, for example, steep from gentle slopes or convex from concave areas. Instead, the method uses a nested-means approach in which the mean value within a window of 10×10 cells is used as a threshold to differentiate steep from gentle or convex from concave. The method produces 8, 12, or 16 classes depending upon whether the gentle slope class is further subdivided once (into two subclasses) or twice (into four subclasses). This method delineates undefined classes whose local meaning and description must be assigned by a postclassification review and interpretation. Examples presented for DEM grids of 1 km, 270 m, and 55 m illustrated that the method produced meaningful and interpretable results across a range of scales.

In landform classification, as in conventional image analysis, there has been a recent trend toward investigating and adopting methods that involve image segmentation, or object recognition, that classify the object rather than classifying an individual pixel. A multiscale image segmentation approach is advocated by Burnett and Blaschke (2003) and Drăgut and Blaschke (2006) because "a multivariate analysis of pixels does not include topological relationships of neighborhood, embeddedness, or shape information."

In contrast to the bottom-up agglomerative approach of per-pixel classifications, such top-down divisive approaches identify significant discontinuities or boundaries at locations of maximum change in attributes. These boundaries define the spatial extent of objects whose attributes can then be determined and used to classify the entire object. The object's attributes can include context, shape, and topological information, such as adjacency or connectivity in addition to typical measures such as slope, aspect, or curvatures.

In conclusion, it is useful to reflect upon the observation of Dehn et al. (2001) that landforms are described mainly in two different ways (i) based solely on their geometry or (ii) based on semantics used to express and capture subjective conceptual mental models. Deng (2007) also differentiated five classes of landform entities according to the degree of vagueness or subjectivity involved in their definition and recognition. Landform entities that were discrete, clearly identifiable, and objective were classified as bona fide objects or prototypical objects. Landform entities whose definition and recognition involved a degree of vagueness and subjectivity were classified as semantic or fiat objects, landform classes, or multiscale objects.

37.4.5 *"p"* Factor

Acquisition of suitable information about parent material for use in digital soil mapping often presents a challenge. The attributes

of parent material that are most often of interest are depth or thickness (deep or shallow), texture (e.g., coarse, medium, or fine), lithology or mineralogy (e.g., base status), age, and mode of deposition.

At present, the most common source of information about parent material for use in soil mapping studies has come from digitized versions of published geological or soil maps. Among geological maps, those that focus on lithology, rather than age or stratigraphy, tend to be more useful for soil prediction. Reinterpretation or recompilation of existing geological maps is often necessary to emphasize lithology in place of the original stratigraphic focus (Lawley and Smith, 2007).

Given that existing geological maps are often unavailable or inadequate, many studies have sought to identify alternative approaches for obtaining or inferring the main parent material attributes of interest. Of these, interpretation of airborne gamma-radiometric data in terms of regolith properties seems to have generated the greatest interest and success (Cook et al., 1996; Wilford et al., 1997, 2001; Pickup and Marks, 2000, 2001; Hardy, 2004; Rawlins et al., 2009). Radiometric data highlight differences in the parent material that can be interpreted in terms of depth to bedrock, mineralogy and lithology, age and mode of deposition. Clear distinctions have been made between transported and in situ regolith and between rocks with varying degrees of weathering. Radiometrics can provide an indication of the degree of erosional and depositional activity, which allows actively eroding surfaces with shallow regolith to be separated from stable surfaces with deeper regolith. Differences in mineralogy show up as different colors and patterns in ternary radiometric images, and these patterns can identify the spatial extent of areas of different lithologies (e.g., base rich versus acidic) and mineralogies (potassium rich granite versus depleted quartz sands). Degree of weathering, related to geomorphic age and amount of transportation, can often be interpreted from radiometric data, with highly weathered materials emitting low responses and recently exposed or weathered materials emitting high levels of gamma radiation. Such distinctions can be used to separate, for example, recent eolian deposits from old, well-sorted and intensely weathered fluvial deposits (Bierwirth and Brodie, 2005). Typically, radiometric data are most effective when interpreted in combination with additional data sources, particularly terrain data as extracted from a DEM (Cook et al., 1996b; Wilford et al., 2001).

Radiometric data are not readily available for many areas. In such cases, researchers have investigated a number of different options for inferring specific attributes of the parent material by interpretation of airborne and satellite imagery of various types and resolutions. The use of imagery for inferring attributes of parent material typically focuses on identifying specific parent material characteristics that are associated with distinct and highly contrasting patterns in the imagery. For example, areas of salinity, affected by gypsic or calcic surface materials, often contrast sharply with surrounding unaffected areas and can be isolated using imagery alone or using a combination of imagery and digital elevation data (Fernández-Buces et al., 2006;

Nield et al., 2007; Rodriguez et al., 2007; Boettinger et al., 2008). Similarly, areas of organic soils (Connolly et al., 2007), wetlands (Peng et al., 2003; Landmann et al., 2006; Wright and Gallant, 2007), and African dambos (Hansen et al., 2009) often contrast sharply with their surroundings and can be isolated using multidate, multispectral digital imagery or multidate SAR (Townsend and Walsh, 1998; Townsend, 2001; Lang et al., 2008; Liu et al., 2008a).

Ground-based measurements of soil's apparent electrical conductivity (ECa) have been widely used to infer properties of the parent material for relatively small areas of field to regional extent. Here the assumption has been that electrical conductivity reflects the combined influence of soil texture, mineralogy and moisture content, and areas of different texture will exhibit interpretable differences in electrical conductivity (Liu et al., 2008b). Additionally, other natural fields of the earth, gravitational, magnetic (Galdeano et al., 2001), and electromagnetic (Beard, 2000), have also been used to provide information on underlying geological structure.

Recent developments have seen increasing interest in modeling spatial variation in parent material classes or parent material properties in a manner that is analogous to *scorpan* modeling of soil spatial patterns (Hardy, 2004; Lawley and Smith, 2007). Pain et al. (2001) and Clarke and Pain (2004) described regolith–landform studies in Australia as being concerned with understanding the 3D distribution of regolith materials, and its representation in map form, rather than vertical profiles or cross sections. They note that regolith is very closely associated with landforms and once the interrelationships between regolith and landforms are understood, landforms can largely be used to predict regolith patterns. Thus, landforms are used as a proxy for the largely hidden regolith. They report that landforms can be identified and delineated in a number of different ways, including conventional air photo interpretation, manual or automated interpretation of remotely sensed imagery, automated analysis of airborne radiometric data, and 3D mapping of the regolith using such techniques as air- and ground-based electromagnetic, ground-penetrating radar, and shallow seismic magnetic surveys. They inferred regolith properties such as texture, mineralogy, depth, and geochemistry by interpretation of the mapped landform classes. It is anticipated that an increasing number of digital soil mapping studies will utilize predictive modeling methods to produce separate predictions of parent material attributes such as depth, texture, and lithology for subsequent use in digital soil mapping.

37.4.6 *"a"* Factor

a represents age or elapsed time. This will give limits on how long pedogenesis has been occurring and should differentiate soil classes and properties. One useful estimate of *a* is the age of the ground surface, which may be very old indeed (Twidale, 1985). Alternatively, *a* can be represented by the age of the material in which soil has developed, suggesting that the *scorpan* approach will not deal well with polycyclic soils. It is theoretically likely

that soil development will follow some logarithmic or square-root time relationship, suggesting more need to differentiate between younger materials than older ones. Schaetzl et al. (1994) discuss the form of soil chronofunctions.

Geomorphologists and stratigraphers can presumably draw maps of *a* independent of soil maps. In fact, such "gues(s) timated" maps along with an estimate of uncertainty could be used to represent this factor. There are methods for soil and material dating of course, for example, ^{14}C, $\delta^{18}O$, thermoluminescence (inter alia, Matt and Johnson, 1996), and $^{40}Ar/^{39}Ar$ (inter alia, Van Niekerk et al., 1999). None of these are, as far as we are aware, capable of scanning and producing full coverage in a true remote sensing fashion. Ground electromagnetic methods have been used for stratigraphic mapping, for example, Sinha (1990). *a* remains difficult to characterize well. Indeed, it seems that more than any factor expert knowledge is still needed to derive *a*. Considerable advances in technology and knowledge are needed.

Scull et al. (2005) used decision tree in the southwestern Great Basin area for predicting soil class. Age of landform is inferred from remote sensing data, which can indicate surface age by detecting desert varnish. They found that the age of landform covariates is an important predictor in the decision tree model. Noller (2010) presented an explicit use of the age factor in digital soil mapping. He estimated geochronological information for Malheur County, Oregon based on independently compiled Quaternary geological maps, age point data, and remotely sensed data. These data were incorporated in decision tree analysis. Expert soil survey maps are used as reference in making predictions with and without implicit or explicit age information. Addition of geochronological data produces digital soil maps that are most closely aligned with expert maps. Improvements in the map are greater in areas where the age stratification of the landscape is not obvious to the soil surveyor.

37.4.7 *"n"* Factor

As was discussed in Section 37.2, soil can be predicted from spatial coordinates alone. Obtaining these is now much easier due to the advent of GPS with 5 m accuracy receivers costing less than $1000. This may indeed reflect some other environmental variable such as climate, and because of this, it can be argued that *n* is not really a factor, but simply organizes the coordinates is a simple way to ensure that spatial trends not included in the other environmental variables are not missed. Therefore, *n* could also be described by some linear or nonlinear (nonaffine) transformation of the original spatial coordinates, for example, a new coordinate could be the closest distance of each location to the coast (Webster, 1977, p. 201), or contextual representation of space, for example, distance uphill from the nearest discharge area (Bui and Moran, 2000), distance from a watershed, distance from roads, distance from a point source, etc. This factor is potentially a valuable yet cheap source of environmental information and should never be disregarded.

37.5 Applications

Having presented a review of what has been done by others and having suggested and reviewed a generic predictive model and potentially useful environmental data layers, we now put this into a framework for soil mapping based on *scorpan* and Soil Spatial Prediction Functions (SSPFs) and spatially autocorrelated errors (**e**). The *scorpan*-SSPFe approach is now outlined with some brief discussion of each of the steps. Its uses, problems, and other implications of the *scorpan*-SSPFe approach are discussed subsequently.

37.5.1 Summary of the Scorpan-SSPFe Method

The *scorpan*-SSPFe method essentially involves the following steps.

   i. *Define soil attribute(s) of interest and decide resolution* ρ *and block size* β

These are the design specifications for the survey. Define soil attribute(s) of interest, that is, a soil property or set of soil properties and/or a set of soil classes, usually from some predefined classification system. The resolution may be defined by the resolution of the environmental variables, for example, 30 m Landsat pixels, but should be a design specification from the intended use of the information. Referring back to Table 37.1, we believe that the methodology discussed here is most appropriate for D3 surveys, therefore pixel or block size ρ, is equal to pixel spacing β and will be in the range 20–200 m. (The linking of ρ and β is a simplification and is a point that requires further study—see Bishop et al. (2001) for further discussion.) At this stage, the uncertainty limits that can be tolerated may be also be defined.

   ii. *Assemble data layers to represent Q*

Assemble the data layers with consideration of the number of layers describing each factor and any prior evidence as to the importance of each factor. This was discussed in detail in Section 37.4. At this stage, we do not know the relative importance of the data layers. Balance is probably important. At this phase of development, because of the relative availability of DEMs, it would be easy to obtain 15 or 50 terrain attributes (*r*), for example, as described in Shary et al. (2002), and rather difficult to represent *a* or *c*. An attempt should be made to represent all the factors however.

   iii. *Spatial decomposition or lagging of data layers*

This is suggested as a step because it is felt that predictions might be scale dependent, and it is important to find the appropriate spatial associations. This can be achieved either by a wavelet decomposition (e.g., Mendonça-Santos et al., 2006), or geostatistically. The geostatistical approach involves modeling the correlation structure in the imagery by decomposing the variogram into independent spatial components, and then taking each component in turn and kriging it, thereby separating it from the others. Oliver et al. (2000) used this approach on SPOT imagery. Both of these

methods will allow the removal of short-range uncorrelated noise components from subsequent sampling, modeling, and prediction stages. The spatial decomposition of the environmental variables begs the question of whether the target attribute should also be spatially decomposed. In most cases, there would probably be insufficient observations to do this effectively, but it could be done where this is not the case.

An alternative approach to spatial decomposition is that of spatial lagging, that is, to fit a model such as,

$$S(x, y) = f(s(x + u, y + v), c(x + u, y + v),...) + g(x + u, y + v),$$

$$(37.22)$$

where the soil attribute of interest is "regressed" on the layers representing the *scorpan* attributes and on spatially lagged ($+u$, $+v$) copies of them, with u and v variable. This approach seems somewhat more cumbersome than the spatial decomposition approach.

iv. *Sampling of assembled data (Q) to obtain sampling sites*
In most cases, soil sampling will be required to set up the model (except perhaps when the aim is map updating). We have a lot of prior information on the environmental variables, which we can use to guide the sampling. The aim is to construct predictive equations for the soil attributes of interest in terms of the environmental variables. This is a kind of calibration exercise, and, therefore, it would seem wise to span the range of values of each variable, so that the prediction model will not be required to extrapolate beyond its bounds. Hengl et al. (2003) proposed sampling along the principal components of the *scorpan* factors; the number of samples taken from each of the components is the proportion of the total variance described by each of the principal components.

Minasny and McBratney (2006) argued that, for the purpose of spatial regression calibration, it would be beneficial to cover the range of values of each of the covariates using LHS (McKay et al., 1979). LHS is a procedure that ensures a full coverage of the range of each variable by maximally stratifying the marginal distribution. LHS involves sampling n values from the prescribed distribution of each of k variables $x_1, x_2,..., x_k$. The cumulative distribution for each variable is divided into n equiprobable intervals. A value is selected randomly from each interval. The n values obtained for each variable are matched randomly with those of the other variables. This method does not require more samples for more dimensions (variables). A conditioned Latin hypercube sampling (cLHS) was proposed by Minasny and McBratney (2006) for sampling of existing covariates or *scorpan* factors. We cannot directly apply conventional LHS to the multivariate distribution of covariates. Sample points selected by conventional LHS may represent combinations of the variables that do not exist in the real world. Randomization is used in this case as the distribution among the variables is not even, and some parts of the variable space might not correspond with existing soil. The conditioned LHS algorithm

attempts to select n observations (sites) from the covariates, which can form a Latin hypercube in the feature space. The algorithm solves an optimization problem: given M sites with covariates (X), select m sample sites ($m \ll M$) so that the sampled sites x form a Latin hypercube. The method is a search algorithm based on heuristic rules combined with an annealing schedule. The objective function to be minimized is an error criterion that counts the occupancy of the hypercube. This kind of sampling should produce a reasonably efficient way of sampling the soil and its environment, so that the range of conditions are encountered, ensuring a good chance of fitting relationships *if they exist*.

An alternative procedure is suggested by the work of Lagacherie et al. (2001) that define a reference area (Favrot, 1989), which through the spatial data layers of the environmental variables extrapolates well to a larger region. Sample the reference area purposively or systematically (fit the model and extrapolate to the rest of the area). This might give a better chance of fitting local relationships with a given sampling effort and should be more efficient in field time—the advantage hinges however on how well the extrapolation can be done.

v. *GPS-field sampling and laboratory analysis to obtain soil class or property data*
Step (iii) yields a set of m spatial coordinates at which the observations of the soil attribute(s) are to be made in the field. These can be located with a GPS receiver, and samples taken for subsequent laboratory analyses, in the usual manner. At a subset of these locations, say 5%, a duplicate observation should be made at a distance (say) half the resolution (ρ) to get an estimate of the short-range field variability in the soil attribute(s). This will help in subsequent spatial modeling. (If a specific purpose or numerical classification or allocation to a conventional classification system is required then the observed soil data can be processed to obtain discrete or continuous class labels for each observation site.)

vi. *Fit quantitative relationships (observing Ockham's razor)*
We can now assemble the soil data for the left side of the *scorpan* equation and the environmental data for the right side. We can now fit the model $f()$ representing the m locations using any of the techniques described in Section 37.3.3. Ockham's razor (the principle that states that "Entities should not be multiplied unnecessarily") should be applied to find the model (with the least number of parameters) that fits best. The residuals (e) of the soil property or class probability or membership at each of m sites should be estimated also (and kriged using either *scorpan*-simple or *scorpan*-compositional kriging as mentioned in Section 37.3.4.2.2).

A single model may not be adequate especially if there are strong pedogeomorphic or geological contrasts within the study area—each subregion may show quite different relationships between soil and environmental variables. In that case, it may be necessary to develop a *scorpan*-SSPFe model for each pedogeomorphic or geological subregion. Care needs to be taken that the prediction surfaces

produced are realistically continuous. This approach demands a higher data burden than a single model for a whole geographic region. Once again the total number of parameters in the final model needs to be considered.

If we have a lot of local information for both sides of the equation (like an existing soil map, or proximally sensed soil data), we can fit a local model,

$$S[x, y] = f_l([x, y]) + e_l(x, y), \qquad (37.23)$$

where the l subscript on $f_l([x, y])$ and $e_l(x, y)$ refers to models fitted to a local (moving) neighborhood centered on $[x, y]$ rather than to the whole area to be mapped. It will be rare that m will be large enough to fit this model. This kind of model was used geostatistically, that is, $S[x, y] = e_l(x, y)$ for soil salinity mapping by Walter et al. (2001).

vii. *Predict digital map*

We now have a model $f()$ fitted to the m locations, which we can now apply to the $(M - m)$ locations where we have no soil observations, but have environmental observations. Additionally, kriging of the residuals (e) at is also done at the $(M - m)$ locations and the results added together. Additionally, the uncertainties of the predictions of $f()$ and e at the M locations should be evaluated. Raster maps can then be made of the soil attribute(s) and their associated uncertainties.

viii. *Uncertainty analysis*

A principal feature of digital soil mapping is the ability to present an accompanying map of uncertainty to the prediction map. However, uncertainty is seldom quantified in digital soil maps. There are two important sources of uncertainty: the uncertainty in the input data and the uncertainty of the spatial prediction techniques.

Uncertainty in the input data can be from the soil data and *scorpan* factors. The uncertainty in soil data is usually much larger than in the covariates. Usually, digital soil mapping uses legacy soil data. Legacy soil data arise from traditional survey, which is generally empirical and based on the mental development of the surveyor. There are no statistical criteria for traditional soil sampling, which may lead to bias in the areas being sampled. Carré et al. (2007) discusses some techniques for evaluating the quality of the legacy soil data based on the *scorpan* factors.

Conventional polygon-based maps often have no uncertainty information. In the Australian Soil Resource Information system, the uncertainty of a soil property is derived from the polygon-based map (McKenzie et al., 2005). This is calculated from a standard uncertainty, which is based on scientific judgment using all the relevant information available, which may include previous measurements on related soils, experience of lab or field or prediction techniques, and assumed from spatial variation.

The major contributing factors to uncertainty in spatial prediction are the neighborhood points used for interpolation: the number and proximity of the samples, clustering of samples, and continuity of the variables. In geostatistics, the usual approach for calculating the uncertainty is by computing a kriging estimate and the associated error variance, which are then combined to derive a Gaussian-type confidence interval. For the regression-kriging approach, the uncertainty has two parts, from the regression model and the kriging of the residuals. See Minasny and McBratney (2007a, 2007b) for mathematical details on this topic.

The uncertainty for prediction of soil classes is more difficult to quantify. Kempen et al. (2009) assessed the uncertainty of the multinomial logistic regression model prediction of soil classes by using Shannon's information entropy. It is calculated based on the probability of the predicted soil classes, the maximum entropy is 1, which occurs when all outcomes have equal probability. The minimum value for the entropy is 0, which occurs when there is no uncertainty and one of the outcomes has probability 1. It should be noted that the entropy indicates whether the predicted soil group has a large probability, it does not indicate that the prediction itself is correct. What is really required is a prediction interval on the prediction probability statement.

Bui and Moran (2003) used a heuristic approach for uncertainty of soil classes. The training area was randomly sampled 10 times. Each time a decision tree was built, and soil classes were predicted into unmapped areas. Where the same class was consistently predicted by several trees, the likelihood is greater that the prediction is consistent (not necessarily correct). The modal class prediction from the 10 trees was used in making the final map. The proportion of predictions resulting in the modal class was used to create a map of uncertainty of the predictions. The map of uncertainty of predictions indicates where the trees have difficulty in capturing the spatial pattern of soils in the landscape.

ix. *Field sampling and laboratory analysis for corroboration and quality testing*

It must not be assumed that the digital information is perfect with minimal information on the quality of the information. Indeed, we cannot expect this kind of map to be more accurate than conventional ones. There are two reasons for this: (i) local variation (at whatever resolution) is a limiting factor, there is a lot of soil variation within 10 m, or 100 m, or 1 km; and (ii) there is uncertainty in environmental layers and this can propagate errors (Lagacherie and Holmes, 1997; Florinsky, 1998; Heuvelink and Burrough, 2002).

Like conventional soil maps, digital ones should also be evaluated for quality. This is the same as ground truthing in remote sensing where many measures have been advocated (see Story and Congalton, 1986; Liu et al., 2006). The main quality criteria for soil class maps are purity (user's accuracy) and producer's accuracy, and root mean square error for continuous soil property maps. These can be evaluated by a number of strategies.

One approach is by cross-validation. Some proportion of the available observations are put to one side, a common

proportion is one-third. Prediction modeling is done with the remaining two-thirds of the data and the map produced. The one-third put aside are now considered test sites and compared with model predictions This can give an indication of producer's and user's accuracy for categorical maps and average bias and root mean square error for maps of continuous soil properties. The results are only indicative because the sample was probably not designed for the express purpose of quality assessment. The results might be somewhat biased for legacy data (Carré et al., 2007), and less so for observations from LHS (Minasny and McBratney, 2006), but still not optimal.

It is better to construct a new sample. Cluster sampling and stratified random sampling have been used in the past for testing the accuracy of conventional maps (De Gruijter and Marsman, 1985; Marsman and De Gruijter, 1986). Kempen et al. (2009) carried out an accuracy assessment of their digitally updated soil map of part of the Netherlands. They observed 150 new points based on a stratified random sampling design with strata based on the original map and found a small improvement in purity from 52% to 58%. They also estimated the purity and producer's accuracy (which they called "sensitivity") for all the units of the new digital soil map.

One of the principal advantages of digital soil maps is the promise of spatialized uncertainty estimators. The quality of the combination of the estimate and its associated uncertainty needs to be tested to properly evaluate digital soil maps. Thus far, this has not been attempted.

x. *If necessary simplify legend, or decrease resolution by returning to (i) or, improve map by returning to (v)*
   If we find the map does not meet design specifications, that is, class purity is less than x%, or the confidence intervals for a soil property are too wide over parts of the map, then we can simplify the legend or decrease spatial resolution (i)—but these should be design specifications, or more sensibly, target further sampling (v) in areas where predictability appears to be poor, and recalculate the maps.

37.5.2 Uses

There are various potential uses of the digital soil mapping approach. Among them are production of digital soil maps as a replacement for the paper-based choropleth soil map of the past, updating existing soil maps, extrapolating existing soil maps into unmapped areas, construction of dynamic soil maps, digital soil assessment, and global soil map.

37.5.2.1 Digital Soil Maps

The main use of the *scorpan*-SSPF approach is to replace the polygon-based soil maps of the past with digital maps of soil properties and classes and their associated uncertainties for areas previously mapped, or for new areas. These maps will be stored and manipulated in digital form in a GIS creating the possibility of vast arrays of data for analysis and interpretation.

The first digital soil maps were simply representations of the observations without interpolation or relation to the environment (e.g., Webster et al., 1979). Some authors have worked on better ways to present digital spatial soil information, chronologically, De Gruijter and Bie (1975), De Gruijter et al. (1997), and Grunwald et al. (2001). This is an area requiring considerable research. One goal must be fully operational multiresolution digital soil maps.

While we cannot necessarily expect the maps to more accurate than conventional ones, we can expect to have a quantitative estimate of the uncertainty (Section 37.5.1); sampling effort should be expended to achieve this. Laba et al. (2002) compared conventional (Congalton and Green, 1999) and fuzzy (Gopal and Woodcock, 1995) methods to assess the accuracy and uncertainty of land cover maps produced at high taxonomic resolution. These methods could be applied to digital soil maps.

Survey commissioners, decision makers and users in general would perhaps be more comfortable with a concept of certainty rather uncertainty. This answers the question, "how well do we know the value at some location?" rather than concentrating on "how badly we know it." A potentially adequate standardized $(0 \rightarrow 1$ or $0\% \rightarrow 100\%)$ measure of certainty is $f = 1 - \min(2s/V, 1)$, where s is the standard deviation of the estimate. For example, if we have an estimate V of clay content of 50% and an s of 5% then $f = 0.8$ or $f\% = 80\%$. More sophisticated measures may be required, such as a certainty characteristic—the probability that a statement C is true within a distance d or an increasing neighborhood A. Clearly, more work is needed on standards for digital soil maps.

A recent advancement in digital soil mapping is the capability to map the distribution of soil properties over the whole soil profile. This created a pseudo 3D distribution of soil properties. Minasny et al. (2006) fitted an exponential decay depth function for soil organic C distribution data in the Edgeroi area in NSW, Australia. Parameters of the exponential function were then mapped using neural networks with some *scorpan* factors as covariates. Carbon storage for any point in the landscape then can be obtained by integrating the exponential function to the desired depth. A more general depth function can be obtained using an equal-area spline (Bishop et al., 1999). Parameters of the spline function can be mapped creating a whole soil profile distribution (Malone et al., 2009).

37.5.2.2 Updating Soil Maps

Digital soil mapping can be used to update soil maps from previous surveys. Models predicting soil classes or series can be built based on legacy soil data (existing soil maps or soil profile descriptions) with *scorpan* factors as covariates. The spatial prediction models can be applied to the entire data. Kempen et al. (2009) used digital soil mapping principles to update the national 1:50,000 soil map for the province of Drenthe (2680 km²) using legacy soil data. Multinomial logistic regression was used to quantify the relationship between ancillary variables and soil groups. The model-building process was guided by pedological expert knowledge to ensure that the final regression model was not only statistically sound but also pedologically plausible.

They estimated actual purity of the updated map, as assessed by the validation sample, was 58%.

37.5.2.3 Interpolation or Extrapolation of Existing Soil Maps

If *s* for a previously mapped region is put on the right of *scorpan* equation, the legend is retained largely, and new samples are collected, this might be considered by some to be map updating. There is another possibility; this is where the previous *s* is put on the left rather than the right side of the *scorpan* equation (an example is given in Bui et al., 1999). The advantage of this is that no new sampling is required for fitting—although corroboration sampling should be done. This would allow quantitative elaboration of the existing (but unknown) models, for classes this is what Girard (1983) referred to as (the usually unknown) "chorological rules," and their subsequent extrapolation to new areas. Possible problems include repeating old models that may be wrong, or extrapolation outside the range of associated environmental data sets—Lagacherie and Holmes (1997) and Lagacherie and Voltz (2000) discuss this for landscapes, while McBratney et al. (2002) were concerned about this for pedotransfer functions. It is also important to establish for which purpose existing data have been collected. Some soil surveyors use auger observations to confirm their mental models, while others use them to find inclusions or boundaries. Therefore, this approach should be used with a deal of caution.

Extrapolation of soil types from one small area to a larger extent can be done once the digital soil mapper knows the initial area is representative of the larger extent (that is why it is usually called "reference area"). This idea, initially proposed by Favrot (1981), has been applied by Lagacherie et al. (2001) for extrapolating French Mediterranean soilscapes. Soilscapes of reference defined as a combination of soil-forming factors in a buffer neighbor can be expressed as a vector composition of elementary landscape classes of different sizes. Since the landscape classes are known to be representative of the overall area, Manhattan distances between soilscapes of reference and composition of landscape classes in running neighboring windows can be calculated. The final allocated soilscape is the one that minimizes the Manhattan distance. Two outputs are then produced in that case:

- The final soilscape map
- The corresponding allocation distance giving access to the accuracy of the final map

This technique allows for minimizing field sampling. However, the main scientific question is where to stop the boundaries of the bigger extent to map?

Bui and Moran (2001, 2003) built decision tree rules in training areas where detailed soil maps were available, and the rules were extrapolated to larger areas where detailed maps were not available. Grinand et al. (2008) tested this approach and observed marked differences in accuracy between the training area and the extrapolated area. They found that sampling intensity did not appear to influence the accuracy of prediction, and spatial context integration by the use of a mean filtering algorithm on the covariates increased the accuracy of the prediction on the extrapolated area.

37.5.2.4 Environmental Change: Partially Dynamic "Scenario" Soil Maps

One major criticism of conventional soil maps is that they are essentially static statements. Digital soil maps created with the *scorpan*-SSPF methodology offer new and necessary possibilities. It is becoming increasingly important for environmental reasons to know not just $S[x, y]$ but $S[x, y, t]$. If we know any of the partial differentials, $\delta s/\delta t$, $\delta c/\delta t$, $\delta o/\delta t$, etc., the first two perhaps being the more important—we can project the existing soil map forward by some time *u* by calculating most simply say $c + u(\delta c/\delta t)$ for all points and running the new *c* layer(s) through the prediction function. "Change-detection analysis" (Mücher et al., 2000) is well developed for land use and vegetation change (components of $\delta o/\delta t$) using remotely sensed imagery and/or aerial photographs average, and localized values of *o* can be estimated from rasterized images taken at two or more times (Munyati, 2000). Other derivatives may be obtained from models (e.g., temperature and rainfall changes) or from a few monitoring stations (e.g., soil changes) within the area of interest (Mendonça-Santos et al., 1997).

This potential approach has limitations compared with a fully fledged dynamic simulation model, such as lack of feedback and possible extrapolation problems, where, for example, $c + u(\delta c/\delta t)$ takes us (well) outside the range of the original training data. Nevertheless, we still have a relatively quick and easy way to produce first-cut "scenario" soil maps of both properties and classes.

The European Parliament is currently implementing a new Directive on the use of renewable energy in Europe. Ten percent share of renewable energy in transport should be achieved by each Member State by 2020. The main source of renewable energy for transport is planned to be biofuel. One scientific aim addressing the sustainability question is then to assess the impacts of such a Directive on global land (soil and above-ground vegetation) carbon stock changes due to indirect land use conversions. After quantifying the biocrops needed to achieve the 10% biofuel share target, land use conversion due to biocrops and transfer of food/feed/fiber crops will be spatially estimated at the global scale. Overlaying the current stock of land carbon with the current land use and targeted land use conversion, climate and land management practices information, it is possible to spatially assess the carbon stock changes within the next 20 years by following the Tier 1 approach of volume 4 of the *IPCC Guidelines for National Greenhouse Gas Inventories* (IPCC, 2006). The main difficulty is not only to estimate uncertainties coming from the modeling (this is provided by the IPCC report) but also to quantify the uncertainties of the different sources of inputs, usually not specified.

37.5.2.5 Digital Soil Assessment

Digital soil assessment is the step following digital soil mapping (Carré et al., 2007). It is the quantitative modeling of difficult to measure soil attributes, necessary for assessing threats to soil (e.g., erosion, decline of organic matter, and compaction) and soil functions (biomass production and environmental interactions) using outputs from digital soil maps, that is, the soil

properties map and the accuracy of the predictions. The threats to soil and the soil functions are generally aspatial models. They require not only data on soil (as provided through digital soil mapping) but also external data that can be also considered as soil-forming factors, and already used as covariates. These can be climate, land cover, or land management practices. DSA requires running the aspatial models, and as for DSM, the prediction of uncertainties coming from input data and the models.

Uncertainty prediction is usually performed using global sensitivity analysis of the models and simulating the distribution of the uncertainties with Monte Carlo simulation (Heuvelink, 1998). Three exercises have been tested for digital assessment problems. The first one deals with soil pollution issue (Romić et al., 2007) using regression-kriging approach and continuous limitation scores for assessing global soil pollution. The second one deals with wind erosion (Reuter et al., not published) combining regression-kriging for the soil properties prediction (used as output for wind erosion). The third one deals with estimation of biomass production in England & Wales (Mayr et al., private communication).

37.5.2.6 Global Soil Map

A Digital World Soil Properties Map consortium (www.global-soilmap.net) has been formed and comprises representatives from universities, research centers, development organizations, and private enterprises around the world. This is a response to the urgent need for accurate, up-to-date, and spatially referenced soil information, at a global scale, as expressed by the modeling community, farmers and land managers, and policy and decision makers. The objective of this consortium is to create a digital map of the world's soil properties at a resolution of 90 m × 90 m to a depth of 1 m based on legacy and newly collected soil data.

Making a digital global soil map is a challenging task, methods for mapping soil properties at a continental or global scale are not straightforward. Moreover, different parts of the world have varying soil information of varying qualities. The soil information can be from legacy soil profile data, existing soil maps, but also data from reflectance spectra. The soil–landscape model will vary from place to place and the knowledge and techniques for regional soil mapping may not be applicable at a global scale.

Minasny and McBratney (2010) summarized a methodology for global digital soil mapping based on legacy soil data. For an area of interest, we assemble all the *scorpan* or environmental covariates and existing soil data. The second step is to check how the soil data cover the covariate space and to select possible training areas.

Methods used for digital soil mapping depend on the availability of soil data, and the possibilities in the order from the richest to the poorest soil information are as follows:

1. *Detailed soil maps with legends and soil point data*
   This is the richest information that can give the best prediction of soil properties. Soil properties can be derived from both soil maps and soil point data. The available methods are extracting soil properties from soil map using a spatially weighted measure of central tendency, for example, the mean, spatial disaggregation of soil maps, *scorpan*

kriging, and combinations of these. An example of such an application is given in Henderson et al. (2001, 2003).

2. *Soil point data*
   When soil point data are available, soil properties can be interpolated and extrapolated to the whole area by using a combination of empirical deterministic modeling and a stochastic spatial component. We called this the *scorpan* kriging approach.

3. *Detailed soil maps with legends*
   When only soil maps are available, soil properties need to be extracted from the maps using some central and distributional concepts of soil mapping units.

4. *No data*
   When no data or soil maps exist in area, we will use an approach we called *Homosoil*, which means that we need to estimate the likely soil properties under the observed soil-forming factors or *scorpan* factors.

37.5.3 General Discussion

We now discuss some general points relating to the *scorpan*-SSPF approach to making digital soil maps.

37.5.3.1 Is This the Right Approach?

As stated at the beginning of Section 37.5.1, this is a proposal, not a fait accompli, albeit based on a significant amount of work and experience worldwide. Whether or not this turns out to be the right approach hinges on a number of factors, not all of them scientific, but we shall deal with those first. Scientifically one could ask a number of questions. Are there other soil-forming factors? Are we missing key variables? For example, have we successfully incorporated hydrological effects? Is the underlying idea of a soil somehow in equilibrium with its environment reasonable enough to be predictive? Or, is the soil too chaotic for prediction by other factors? Will the proposed methodology give similar answers as traditional approaches, and do we want it to? Further experiment and experience will undoubtedly answer these questions.

There are other socio-economico-political factors that will have a bearing also. The sociopolitical factors demand recognition of, and solutions to, environmental problems. We believe that the approach has the right kind of economics; it is potentially cheaper than traditional approaches and gives the desired kinds of information. Most of the hardware and software tools are in place to put this approach into practice. Clearly, integrated systems have to be devised. Research into aspects is always needed, principally efficient sampling designs and useful certainty estimation. The biggest stumbling block is identifying and assembling the teams of personnel with the skills required to complete the task. Education of skilled and knowledgeable personnel for those teams is a key priority.

37.5.3.2 Dangers: Let the User Beware!

There are real dangers with this, or any new approach, if it is misused or abused. Here, we outline briefly some obvious pitfalls.

1. *Data quantity and quality.* The first danger is not using enough real soil observations to fit the models, or with using poor quality (missing or noisy) predictor variables. This can, to a degree, be handled by uncertainty analysis—a large topic (Heuvelink, 1998), which has not been discussed formally in this paper. There is a lower limit below which any fitted models will be meaningless.

2. *Overfitting the data.* It is easy to overfit models; this could be because of lack of observations but is more often due to a lack of parsimony, especially a problem for tree-based methods. Overfitted models predict poorly. It is imperative to apply Ockham's razor—this will help with evaluating poorly fitting or overfitted models. The use of cross-validation, pruning, and boosting methods (Hastie et al., 2009) might also help.

3. *Circularity.* A third hazard comes from the possible circularity of the model, for example, a DEM producing climate surfaces producing soil variables as an input to soil class prediction. Once again uncertainty analysis will help.

4. *Databases and data mining.* During the past decade, soil scientists have created regional, national, continental, and worldwide databases. Data mining is a phrase for a class of database applications that look for hidden patterns in such groups of data (Hastie et al., 2009). (Unfortunately, the term is sometimes misused to describe software that presents data in new ways.) Proper data mining software attempts to discover previously unknown relationships among the data. Data mining is a broad concept from supervised learning (prediction) to unsupervised learning and includes all the methods described in Section 37.3.3—neural networks, classification trees with boosting. There are a large number of commercial software products available to do this. They incorporate one, or often several, of the methods described in Section 37.3.3. This will make evaluation difficult as different soil science groups use different software products for fitting $f()$; therefore, comparative studies will be important to evaluate the best approaches. In addition, large national or international databases of legacy soil data will be available (e.g., Bui and Moran, 2003); they also have potential problems because of their unknown site selection probabilities—which are not usually equal—some of the data from Britain where a 5 km grid survey has been completed, are an exception!

37.5.3.3 A New Paradigm?

Hudson (1992) described soil survey as a paradigm-based science. Paradigm is a much overused and hackneyed word these days but it has a precise philosophical meaning. (Much of the following two paragraphs is paraphrased from Rosenberg, 2000.) Paradigm is a term employed by Kuhn (1996) to characterize a scientific tradition, including its theory, apparatus, methodology, and scientific philosophy. The soil scientist's task is to apply the paradigm to the solution of problems. Failure to solve problems is the fault of the scientist not the paradigm. Persistent failure makes a problem an anomaly and threatens a revolution, which may end the paradigm's hegemony.

What is the difference between the *scorpan*-SSPFe approach and the conventional Jenny-landscape model? Both are models—they are simplified descriptions of regularities governing a natural process, usually mathematical and sometimes derived from a more general or simplified theory. Ontologically, they are similar—they both require soil objects and attributes, which are a function of their environment. The conventional paradigm is a qualitative theory. The approach outlined here is a quantitative, partially deterministic, partially probabilistic, empirical theory. So methodologically, they are quite different. The apparatus is also different; here, we require digital information, computers, GIS, etc. The Jenny-landscape model may fall under the *deductive-nomological* model of scientific explanation but, because of its somewhat probabilistic nature, the *scorpan*-SSPFe approach may fall under the *inductive-statistical* model of explanation (Rosenberg, 2000). So the *scorpan*-SSPFe approach to soil mapping probably represents an emerging paradigm eventually leading to a complete paradigm shift.

This begs the question, does $f()$ have to be empirical? The Vienna school of logical empiricists would be generally happy with *scorpan*-SSPFe approach, although perhaps they would have difficulties with its partially probabilistic nature. The lack of a mechanistic theory for predicting soil tugs at the soil scientist's cloak of explanation. Perhaps this is an unnecessary concern; philosophical empiricists believe that there is nothing to causation beyond a regular sequence. Any testing of the mechanistic theory will require empirical observation of the real world. The first attempts at a mechanistic approach have begun but it will be a long time before the mechanistic theoretical approach will be competitive in the predictive sense.

37.5.4 Working Group on Digital Soil Mapping

The Working Group on digital soil mapping (www.digitalsoilmapping.org) was formed in 2005. It operates under the auspices of the Commissions on Soil Geography (C1.2) and Pedometrics (C1.5) of the International Union of Soil Sciences (IUSS). The workgroup has biennial workshops on Digital Soil Mapping. The first workshop was held in Montpellier, France in 2004. The outcome of the workshop is published as a book: Digital Soil Mapping: An Introductory Perspective (Lagacherie et al., 2006). The second workshop was in Rio de Janeiro, Brazil in 2006. The outcome of the workshop is published as a book: Digital Soil Mapping with Limited Data (Hartemink et al., 2008). The third workshop was held in Logan, the United States, in 2008 with an outcome: Digital Soil Mapping: Bridging Research, Environmental, Application, and Operation (Boettinger et al., 2010). The fourth workshop was in Rome in 2010.

37.6 Conclusions

We have reviewed various approaches to predictive modeling and data acquisition and proposed a framework and a methodology for producing digital soil maps.

37.6.1 Summary of the Method

The *scorpan*-SSPFe method essentially involves the following steps:

i. Define soil attribute(s) of interest and decide resolution ρ and block size β
ii. Assemble data layers to represent *Q*
iii. Spatial decomposition or lagging of data layers
iv. Sampling of assembled data (*Q*) to obtain sampling sites
v. GPS-field sampling and laboratory analysis to obtain soil class or property data
vi. Fit quantitative relationships (observing Ockham's razor) including spatially autocorrelated residual errors
vii. Predict digital map
viii. Perform uncertainty analysis
ix. Field sampling and laboratory analysis for corroboration and quality testing
x. If necessary simplify legend, or decrease resolution by returning to (i) or, improve map by returning to (v)

All of the hardware and software tools, technologies and knowledge, are in place to make this approach operational. This is clearly an exciting time for soil resource assessment.

37.6.2 Future Work: Open Questions

Clearly, we need to try out the methodology outlined above and by experience we shall discover the useful forms of *f*() and the serviceable *Q* layers. These are the key open questions. In summary, topics to be further researched include the following:

1. Environmental covariates for digital soil mapping
2. Spatial decomposition and/or lagging of soil and environmental data layers
3. Sampling methods for creating digital soil maps
4. Quantitative modeling for predicting soil classes and attributes (including generalized linear and additive models, classification and regression trees, neural networks, fuzzy systems, expert knowledge and geostatistics)
5. Quality assessment of digital soil maps
6. (Re)presentation of digital soil maps
7. Economics of digital soil mapping

Nevertheless, we believe the methodology can be used now for real-world applications.

Soil Change in the Anthropocene: Bridging Pedology, Land Use and Soil Management

Daniel deB. Richter, Jr.
Duke University

Arlene J. Tugel
United States Department of Agriculture

38.1 Overview and Objectives

Pedology is the science of soil change. Historically, this meant that pedology was mainly a basic science of natural soil processes and soil formations. Today, in the new geologic epoch that Crutzen (2002) has named the Anthropocene, pedology is fundamentally challenged to bring humanity entirely within the soil continuum (Dudal et al., 2002). During this period in which humanity exerts growing and predominant influence over Earth's systems, and especially Earth's soil (Yaalen 2000), pedology is becoming a much more interdisciplinary science with basic and applied objectives, one that requires the natural and social sciences but also the humanities (Richter, 2007).

In this chapter, discussions of "soil change" focus on the domestication of Earth's soil over historic time, the transformation of soil into a cultural-historic-natural system. This chapter describes human-altered soil processes and the forcing factors that are fundamentally changing soils across the planet, for like it or not, soils now serve as parent materials for humanity's accelerating influence. Humanity's impact on Earth's soils can now be called "global soil change" (Arnold et al., 1990).

The objectives of this chapter are to review the history of pedology as it responds to the challenges of the Anthropocene, consider soil change as it impacts soil function and ecosystem goods and services, evaluate the approaches to the study of soil change, enumerate on the factors and mechanisms affecting soil change that will improve prediction and management, and speculate on the future science, inventory, and management of soil change, specifically in the next few decades. The evolution of pedology is briefly described from its time as a basic, natural science that was focused narrowly on soil as a relatively slowly changing natural system, to its present and future as a broadly interdisciplinary environmental science that quantifies and predicts human-affected soil and soil-environment change on human timescales (years, decades, and centuries). More than anything, this chapter means to encourage the pedological community to redouble and expand the work of its pioneers such as Hilgard (1860), Darwin (1882), Dokuchaev (1883), Jenny (1941, 1961), Bidwell and Hole (1965), and Yaalon and Yaron (1966) to further integrate humanity as agents of soil formation, evaluate humanity's effects on soil function, and quantify and predict soil responses to human influence with smaller margins of error. We see this historical development as being entirely in parallel with the conceptual development of Earth's critical zone (National Research Council, 2001; Wilding and Lin, 2006), an integrative concept of the near-surface environment, first articulated by the landmark National Research Council (2001) report on the future of the earth sciences.

38.2 A Brief History of Human Influence on Soil

Soils have been used for agricultural and engineering purposes for at least 10,000 years. Human influence on soil was probably first affected by fire, but over the Holocene effects included a wide range of agricultural impacts; construction of villages, cities, and roads; leveling and terracing; irrigation and drainage; mining; and compaction and compaction and erosion. Human action is often goal oriented and is strongly affected by culture.

Human use, impact, and reliance on the soil are nothing short of staggering, and today with more than 6 billion persons on Earth, we look to the prospect in only a few decades of 10 billion persons (FAO-STAT, 2009). Over 2 billion Mg (metric tons) of cereals are harvested from soils per year, and over 1 billion Mg of vegetables plus roots and tubers; and from animals, over half billion Mg of milk, a quarter billion Mg of meat, and 50 million Mg of eggs; and from forests, more than 3 billion Mg of wood for fuel wood and industrial products. Currently, over 100 million Mg of N, P, and K are applied each year (increasing by three- to eightfold since 1960); about 250 million ha are irrigated, an area that has about doubled since 1970; and on the order of a million hectares of land is severely disturbed each year by mining. The growth of humanity's numbers and affluence means that these products of the soil will be doubled in the coming few decades and century. Both the extent and intensity of soil management are thus substantially increasing, and by any measure, we are pushing the Earth's soil very hard indeed.

More than half of the Earth's 13 billion ha of soil are today plowed, pastured, fertilized, limed, irrigated, drained, fumigated, bulldozed, puddled, compacted, eroded, leached, mined, reconstructed, or converted to new uses. Like it or not, humanity has become a major factor in soil formation and can prompt

TABLE 38.1 Soil Properties Grouped Qualitatively According to Rate of Change in Response to Human Forcings Such as Common Agricultural and Forestry Practices, Regional Air Pollution, Alterations in Hydrology, or Climate Change

Dynamic		Persistent
10 Years	$10–10^2$ Years	$>10^2$ Years
Acidity and salinity	Fragipans	Texture
pH-dependent charge	Fe/Al oxides	Rock volume
Bulk density and porosity	Occluded fractions of C, N, P	
Bioavailability of macro- and micronutrients and contaminants	Eluvial clay	
	Non-pH dependent charge	
	Fragipans, duripans, and plinthites	
Infiltration and hydraulic conductivity	Stabilized humic substances	
Rooting depth and volume		
Aggregates and structure		
Redoximorphic features		
Labile fractions of organic carbon		

change through single events such as tillage or prolonged phenomena such as global climate change. A number of soil properties are responsive to common agricultural or forestry practices, regional air pollution, and alterations in hydrology and landforms (Table 38.1). Two general patterns are evident: Most soil properties are *dynamic*, that is, significant changes can occur over timescales of centuries, decades or less, and only a few are relatively static or *persistent,* that is, properties that are little affected by human forcings. Table 38.1 is most striking perhaps for how it illustrates that so many important soil properties are susceptible to change on timescales of decades or less.

38.3 Pedology, Anthropedology, and Earth's Critical Zone

Of the widely recognized five soil-forming factors, pedology has historically treated organisms nearly always without humanity, except as an actor that disturbs, interrupts, manipulates, truncates, arrests, or subverts the natural process of soil formation. Yet, like it or not, human influence on soils worldwide has increased so extensively in the past few decades that there is now no alternative but to embrace humanity as part of the soil system, (Amund & Jenny 1991) even to recognize human influence as a sixth soil-forming factor (Amundson and Jenny, 1991; Dudal et al., 2002).

Viewed from the perspective of the Anthropocene (Crutzen, 2002), pedogenesis and morphology have for too long overemphasized the natural environment to the neglect of humanity as a soil-forming factor (Dudal et al., 2002; Ibáñez and Boixadera, 2002). Most soil surveys provide little information about the response of dynamic soil properties, such as organic matter, bulk density, and aggregate stability, to management and the effects of these changes on soil functioning. Despite this critique however, the historic pedological emphasis on the natural environment is understandable given how daunting the tasks for traditional pedology have proven (e.g., Richter and Babbar, 1991; Lal and Sanchez, 1992). Soil, the subject of pedology, has been documented to possess extreme spatial diversity from local to global scales, a diversity derived from high-order interactions of soil-forming factors. Soil is described as the most unparsimonious of all Earth's natural entities according to Johnson (2005), and the most complex of Earth's biomaterials according to Young and Crawford (2004).

One of pedology's most challenging tasks, however, is to understand how soils function and develop over human timescales. While soils can be destroyed and reinitiated in a moment's passing due to floods, mudflows, wind storms, volcanic ejecta, earthquakes, or a plow or a backhoe, soil formation also plays out over incredibly long sweeps of time. In the natural environment, stream terraces stable for even 1000s of years have soils that are youthful, whereas ancient soils are distinguished if they develop and survive for millions of years on biogeomorphically stable landforms. With soils ranging so widely across time, it is understandable why pedology has traditionally considered humanity to be more an

interruption than an integral part of soil formation. Yet in response to humanity's growing influence on Earth's systems, Bidwell and Hole (1965) and Yaalon and Yaron (1966) forcefully argued that pedology needs to embrace the vast activities of humanity. Bidwell and Hole (1965) considered not only hunting, gathering, and cultivation as integral to soil formation, but also watershed management and planning. And when Yaalon and Yaron (1966) used the term "metapedogenesis" that described human alteration of soil, pedology became a science of human-soil interactions.

Pedologists in the Anthropocene thus conceive of soil differently than did Hilgard (1860) and Dokuchaev (1883), whose pedological frontiers were focused explicitly on the natural formation of "virgin soil" according to Hilgard (1860). In the Anthropocene, pedology must increasingly focus on the science, inventory, and management of domesticated soils for purposes related to food production, human safety, and environmental quality. Because of the significance of this shift of focus, Yaalon and Yaron's (1966) ideas about anthropedogenesis can be recognized to be as fundamental to the development of pedology as the original model of soil as a natural body, attributed to Dokuchaev and Hilgard over a century ago.

No longer can soil be portrayed as it was in the past: as a relatively static component of ecosystems or as one formed by processes that do not include humanity. Recent pedological studies show how soil in the Anthropocene is a dynamic natural, historic, and cultural system subject to fundamental changes on human timescales. Boxell and Drohan (2009) found changes in soil morphology and physical properties with potential for increased runoff and erosion after *Bromus tectorum* L. (cheatgrass) invasion of a native sagebrush ecosystem in Western North America. After an evaluation of mature *Pinus palustris* Miller (longleaf pine) stands and intensively cultivated land use systems in the southeastern United States, Levi et al. (2010) discovered that near-surface soil properties were more similar by land use than by taxonomic-based soil map units.

Soil is an integral and interactive part of the rapidly changing ecosystem and wider environment and an important component of Earth's critical zone (National Research Council, 2001; Wilding and Lin, 2006), the solid surface of the planet where life is sustained by the interactions of physical, chemical, and biological processes in well integrated above- and belowground environments. Information about human impacts on these dynamic systems is needed to evaluate and predict the effects of land use and management on soil and its capacity to function. Recently, a new USDA-NRCS soil survey program was initiated to gather information about soil change in order to define potential and achievable values of dynamic soil properties for specific soils under a variety of management systems (Tugel et al., 2008).

38.4 Soil Change and Soil Function

Of great interest to anthropedologists are changes in soil functions in both natural and managed systems. Soil functions are described by what soil does and by how soil sustains, regulates, and controls the many biotic and abiotic processes in Earth's

pedosphere. In the Anthropocene, soil functions and ecosystem services are often parallel concepts for the evaluation and management of human impacts on ecosystems. Soil functions and ecosystem services have developed into critical discussions not only in the soil sciences literature but also in the literature of environmental change, ecosystem ecology, biogeochemistry, and land management. The general similarity of these concepts across disciplines is striking.

Soil functions relating to plant production, human and animal health, and the environment are widely discussed in the soil quality literature (Larson and Pierce, 1991; Parr et al., 1992; Blum and Santelises, 1994; Doran and Parkin, 1994; Karlen and Stott, 1994; Acton and Gregorich, 1995; Warkentin, 1995; Harris et al., 1996; Seybold et al., 1997; Carter et al., 2003; Andrews et al., 2004) and include (1) sustaining biological activity, diversity, and productivity; (2) regulating water and gaseous flows; (3) retaining and processing nutrients, organic compounds, and pollutants; (4) resisting structural and physical degradation; (5) partitioning and processing energy; and (6) supporting aesthetic and cultural attributes. For soil survey inventories, the emphasis is on fundamental functions such as nutrient and elemental cycling, hydrologic functions, and providing a medium for plant growth (Tugel et al., 2008).

The Millennium Ecosystem Assessment (Hassan et al., 2005) provides a broad definition that does not explicitly identify soil functions but alludes to them as supporting services. The report defines ecosystem services, some of which are soil functions, as follows: "Ecosystem services are the benefits people obtain from ecosystems." Soil functions are ecosystem services that include (1) provisioning services such as food and water (products); (2) the regulating of floods, drought, land degradation, and disease; (3) cultural services such as recreational, spiritual, religious, and other nonmaterial benefits; and (4) supporting services such as soil formation and nutrient cycling, which are essential for the production of provisioning, regulating, and cultural services. In a discussion of the economic valuation of services provided by natural ecosystems, Daily (1997) specifically describes services provided by soil, such as the physical support of plants, and places a value on that service using costs of a replacement practice, such as hydroponics.

In landscape assessments, Tongway and Ludwig (1997) use the term "functional" to describe how landscapes capture, retain, and use water and nutrients. In the procedures described in *Interpreting Indicators of Rangeland Health*, soil functional status is evaluated for biotic integrity, hydrologic function, and soil and site stability (Pyke et al., 2002; Pellant et al., 2005).

Across these definitions of soil function, the consequences of change are paramount. Arnold et al. (1990) suggest that the significance of soil change depends mainly on its reversibility. Irreparable change can compromise the ability of land managers to enhance or maintain soil functional capacity, produce goods and services, and minimize adverse effects on the environment. Minimizing the negative consequences of change so that future management goals and soil functions are not compromised is an overarching goal for long-term soil conservation and ecosystem

management and a primary concern with respect to soil degradation (Oldeman and van Lynden, 1997, Gerasimova et al., 2000). Inventorying and disseminating information about soil change and its consequences is a new challenge for soil survey.

38.5 Scientific Approaches to the Study of Soil Change

Because so many soil changes play out over years and decades (Table 38.1), special approaches are needed to quantify these dynamics. Although an understanding of soil change is vital for sustained land management, we cannot readily predict many soil changes with our current knowledge. Moreover, since soil changes result from high-order interactions of biology, chemistry, and physics, quantification of soil change requires direct observation of specific soils and their responses to management, at research sites over periods of decades. However, direct observation of changes over time in particular soils has been feasible for only a few soils. Five alternative and complimentary approaches are discussed: (1) long-term soil–ecosystem experiments (LTSEs), (2) short-term soil experiments, (3) space-for-time substitutions (SFTSs), (4) long-term resource monitoring (LTRM), and (5) computer models.

LTSEs are studies used to observe whole soil systems as they respond to controlled management regimes. To more fully understand the Earth's soil and its relations to the larger environment, there is no substitute for long-term observation, and repeated sampling, archiving, and analysis, in studies that pass from one generation of scientists to the next. Such foresighted research is challenging to establish and sustain. The first global inventory of such studies is being accumulated with descriptive meta-data on a real-time Web site (www.ltse.env.duke.edu).

Long-term experiments provide the base lines for understanding how and why soils change through time, for estimating rates, lags, and thresholds of change, and for documenting soil's resilience. However, long-running experiments are difficult to initiate and sustain; they require organization, data management, and unusual collaborations among scientists, even across generations. Long-term studies are susceptible to neglect or abandonment, and even productive LTSEs such as those described by Farina et al. (2000a, 2000b) in southern Africa can be summarily terminated simply due to an absence of interested scientists. Although LTSEs can be initiated with enthusiasm and the best of intentions, they may be terminated by lack of funding, shifts in research priorities, or societal instability.

Compared with complex experiments that require much labor and expense to maintain, long-term experiments that are labor efficient and straightforward in design are most likely to survive the tests of time. Even still, scientific returns from LTSEs may be few during their early years, and though challenging, the cycles of field work, samplings, archiving, and analyses must be balanced by scientific achievements. Long-term soil experiments face technical challenges as well (Steiner, 1995), as, for example, sampling soil with precision and accuracy is rarely easy and the statistical designs of many LTSEs can be questioned (Loughin,

2006). Some experimental treatments such as cultivation may eventually undermine the integrity of the experiment itself (Sibbesen, 1986). The representativeness of LTSEs is also not a trivial issue; for example, Debreczeni and Körschens (2003) estimated that >70% of the world's long-term field experiments are in Europe, and a recent web-based inventory of LTSEs (Richter et al., 2009) indicates that >80% of LTSEs test agricultural objectives and that >50% of these studies are located on relatively level Alfisols and Mollisols, many of which have remarkably high native fertility. Steiner (1995) suggested that the reason why so few long-term experiments test marginal soils was due to the unsustainability of such studies.

While LTSEs may be instrumental and necessary to the study of soil change they are by no means sufficient. Long-term studies need to be complemented by short-term soil–ecosystem experiments (STSEs) in the laboratory and field; by broadly focused SFTSs; by LTRM programs; and by computer modeling. Each is summarized in Tables 38.2 and 38.3 and discussed in detail in the following paragraphs.

STSEs in the lab and field include most studies of soils that are conducted up to a few years in duration. Nearly all of the sciences of soil physics, chemistry, and biology have been built from data arising from STSEs. Yet ironically, while STSEs often explore soil processes such as aggregation, adsorption, complexation, carbon dynamics, weathering, microbial activity, redox reactions, and soil fertility itself, extrapolating soil change over decadal timescales becomes a major challenge for STSEs. Small errors scaled across many years can readily bias long-term projections. Although STSEs can greatly enrich soil concepts and models, most are reductionist (isolating individual components

TABLE 38.2 Five Major Approaches in the Science and Management of Soil Change

Approach	Time Scale (Years)	Strengths	Limitations
STSEs	<1–10	Field or lab based, experimental control, versatile, short-term process	Extrapolation to larger scales of space and time, reductionist
LTSEs	>10	Field based, direct observation of whole soil system, experimental control, sample archive	Duration before useful data, vulnerable to loss, extrapolation to larger scales
SFTSs	>10–1000	Field based, highly time efficient	Temporal responses confounded entirely with spatial variation
LTRM	>10	Field based, direct observation, regional perspectives, sample archive	Complex planning and operational details, expense, no experimental control, duration before useful data
Computer models	<1 to >1000	Versatile, heuristic, and predictive, can support all other approaches	Dependent on quality of observational data

TABLE 38.3 Suitability of Measurement Approaches for Documenting Soil Change

Soil Change Attribute	Measurement Approach			
	STSE	LTSE	SFTS	LTRM
Variable at steady state (dynamic soil property)	R	S	M, R	S
Rate				
Short-term	F, R	F		F
Long-term		S	N	S
Fluctuation				
Short-term	F, R	F		F
Long-term		S		S
Trend, long-term		S		S
Pathway of change, feedback, thresholds, and hysteresis				
Short-term	F, R, S	F, S		F
Long-term		S	N	S
Resistance				
Short-term	R, S	S	M, R	S
Long-term		S	M, N	S
Resilience				
Short-term	R, S	S	M, R	S
Long-term		S	M, N	S

The three techniques, STSEs, LTSEs, and SFTSs, include experimental designs to facilitate comparisons among different treatments or kinds of land uses. LTRMs are not commonly designed to make comparisons among monitored sites or conditions but rather to simply track trends over time. Quantifying rates, pathways of change, and thresholds generally requires long-term studies or monitoring.

F, suitability depends on measurement frequency; M, suitability depends on management history at location sampled; N, suitability depends on the number of age classes sampled; R, suitability depends on characteristic response rate of the variable measured; S, suitability depends on time span over which repeat measurements are made. No entry indicates poorly suited.

and reactions), and do not examine the whole soil, complete with its high-order interactions and lag times that become apparent only with time in LTSEs. Even still, if STSEs are performed in conjunction with LTSEs, they can provide critical short-term process data important to the interpretation of longer-term soil change. Examples of short-term process data describe the seasonal dependence of nutrient mineralization, the depth-dependence of soil water chemistry, the rate at which annually produced plant-organic matter is harvested or returned to the soil as detritus, or management susceptibility of biologically mediated aggregate formation.

SFTSs, also called *chronosequence studies* or soil comparison studies, are used to efficiently examine temporal change in soil, ecosystems, and landscapes (Pickett, 1989; Hotchkiss et al., 2000). For questions of how soils change with time, SFTSs sidestep the great burden of LTSEs, the need for time itself to pass to directly acquire the information about soil change. One of the most well-known examples is that of Jenny's Mendocino Staircase in California, which is a set of marine terraces tectonically raised over the duration of the Pleistocene, with all soil-forming factors except time assumed to be similar (Jenny, 1980). The SFTSs are especially well suited for studies of change over geologic time and as such they are widely used to describe soil and ecosystem change over multimillennia (Jenny, 1980). SFTSs are, however, indirect in their inquiry, purposefully confound space and time, but thereby leave open the possibility for entirely faulty interpretation if misused. As an example, in a study of soil formation on mine reclaimed land, a poorly designed SFTS with improper site selection might over- or underestimate rates of soil formation on acidic mine spoils if recent soils are composed of parent materials with greater or lesser acidity than those used for older soils (Pickett, 1989). Many scientists are skeptical about the use of SFTSs (Gleason, 1927; Hotchkiss et al., 2000; Buol et al., 2003). On the other hand, only SFTSs can describe many soil changes that operate over many centuries and, if carefully designed to control for physical environment, are useful for documenting change in situations where repeating observations is not feasible (Ballantine and Schneider, 2009).

Carefully initiated comparison studies are being used in the soil survey programs of the Natural Resources Conservation Service to document land use and management effects on dynamic soil properties (Tugel et al., 2008). These studies apply the SFTS technique to make statements about change over time. They manage the limitations owing to variable historical conditions and inherent spatial variability of soil properties by restricting study sites to those with similar management history on closely similar soil and by replicating data collection across multiple spatial and temporal scales. They use state and transition models or other simple conceptual models of cause and effect to derive testable hypothesis and organize results. Selecting extensive soil map units for soil survey comparison studies as well as other SFTSs, LTSEs, and STSEs facilitates the extension of results across broad areas. LTRM programs are designed to document regional or national trends in soil resource condition over time. National monitoring programs generally use a random sampling procedure to select permanent monitoring sites where repeated observations of land use and resource condition are made at multiyear intervals. The tremendous cost of field sampling at all monitoring points is a major barrier to national scale soil monitoring programs. The Forest Inventory and Assessment reduced field sampling after initial efforts (Bechtold and Patterson, 2005) and the Natural Resources Inventory conducted field data collection for a few selected regions on an exploratory basis (Brejda et al., 2001). Vital Signs monitoring programs of the National Park Service were initiated in the early 2000s and to date have limited data to report (Fancy et al., 2009). Long-term monitoring is not limited to national scale monitoring programs. Some land managers monitor specific fields, pastures, timber stands, and other ecosystems as a part of their overall operations. Typical monitoring objectives will vary with the situation and include (1) evaluation and documentation of the progress toward management goals, (2) detection of changes that may be an early warning of future degradation, and (3) determination of trends for areas in desired condition, at risk, or with potential for recovery (Elzinga et al., 1998; Herrick et al., 2005; Madson et al., 2006).

Monitoring data produced by individual land managers are generally site specific in terms of objectives and properties measured and can be difficult to extrapolate. Compared with LTSEs, national resource monitoring programs quantify changes in soils not under experimental control but at randomly selected points across the landscape. Such LTRM programs thus have the potential to quantify soil change regionally as affected by shifts in regional land uses or other environmental conditions. But because management practices are not controlled, LTRM programs are challenged to interpret causes of observed dynamics. Causes of regional changes in soil carbon in two notable LTRM programs in England and Wales (Bellamy et al., 2005) and across Belgium (van Wesemael et al., 2004) have been controversial (Smith et al., 2007).

Computer models offer an approach to understanding soil change from the instantaneous to the multimillennial (Parton et al., 1987; Bouma and Hack-ten Broek, 1993; Pulleman et al., 2000; McBratney et al., 2002). The role and rationale of models are as much heuristic as they are predictive, as they represent refined hypotheses and depend on linkages with empirical studies. Models are instrumental for making progress in understanding soil change whatever the timescale, and are most convincing when simulation results are comparable with observational data. Whether observations are from LTSEs, STSEs, SFTSs, or LTMP's, empirical data are critical for gauging model competence and performance.

38.6 Forcing Factors, Process, Resistance, and Resilience

Understanding the causes of soil change and their effects on function requires interdisciplinary analysis at multiple spatial and temporal scales (Dent et al., 1996) as well as reductionistic basic research (Bouma, 1997). The challenge of studying open, dynamic systems is that there are few simple cause and effect relationships. Yet, motivating the study of soil change is the understanding that humanity is an integral part of the soil system, an agent affecting the flow through soils of energy, water, gases, and solid materials (Bidwell and Hole, 1965; Yaalon and Yaron, 1966), not simply an external player disturbing or perturbing the system (Goudie, 2005). Human activities impose a variety of forces on soil to affect the processes essential to the production of goods and services. This section provides a brief discussion on how forcing factors and processes involved in soil change are described by various disciplines. Also included are perspectives on the soil's ability to resist and recover from such forcings.

38.6.1 Forcing Factors

Forces driving ecosystem change are commonly described as forcing factors, stressors, disturbances, and perturbations. Although forcings often have negative connotations, their impacts can of course be positive or negative. Stressors and disturbances refer to factors that cause significant changes in ecological processes as well as the plant, soil, and animal components in ecological systems (Barrett et al., 1976; White, 1979). Stressors are forces that can be continuous, cyclic, or intermittent and include climate change, prolonged drought, agricultural impacts, grazing, fire suppression, and proliferation of invasive species. We use "disturbance" to represent relatively discrete events in time. Each occurrence of the following is an example: plowing, fertilization, irrigation, brush removal, fire, flooding, short-term drought, high-intensity storms, and wind storms. Stressors have a number of features in common. They can be either natural or anthropogenic and an integral feature of natural systems or a necessary operation in managed systems. Forcing factors can also produce direct impacts on small to large areas, which can lead to impacts on other areas. For example, climate change, the cumulative result of many forcing factors, will impact the soil system on large and small areas.

Disturbance regimes, such as recurring fire or flooding, or repeated tillage of agricultural fields are characteristic of many systems. A change in frequency or intensity of a forcing factor can place new stresses on a system. Five attributes are used to define disturbance regimes: disturbance type, spatial scale, intensity, frequency, and predictability (Herrick et al., 1999). A disturbance matrix can be constructed to help compare and understand the effect of disturbances on process (Table 38.4). In this example, fire, logging, and grazing remove aboveground vegetation that affects the supply of organic matter to the system. Logging, grazing, and vehicle traffic may compact the soil, thereby affecting runoff, water availability, soil aeration, and nutrient return to the system. In the Anthropocene, disturbance can also include an absence of fire, as fire has been removed from the landscape over many 100s of millions of hectares with major effects on soils and ecosystems.

The length of time required for a soil to change in response to outside forces is widely variable. It may take decades or longer for the cumulative effects of stressors to cause a functionally important change in soil. Discrete disturbance events, however, can precipitate almost immediate change such as the decrease in soil bulk density that occurs with the first tillage operation of the growing season (Pikul et al., 2006). Episodic events, such as hurricanes and drought, are events that may trigger a shift in systems that have experienced gradual change resulting from long-term management impacts (Scheffer et al., 2001). The combined effects of discrete events and longer-term stress can sometimes be devastating, such as those experienced in the Dust Bowl when continuous cultivation and prolonged drought were followed by intense wind storms.

38.6.2 Soil Processes

Predicting and managing the effects of human actions on soil function and ecosystem services require a detailed understanding of processes that operate within the pedosphere. However, there is tremendous complexity in the processes involved in soil change. Ross (1989) describes four increasingly complex and interlinked soil processes: (1) processes that form soil materials,

TABLE 38.4 Disturbance Matrix Illustrating a Classification of Disturbances and Their Effects on Soil Properties and Processes

Event	Pattern	Biomass Removal	Soil Compaction	Nutrient Return Form	Nutrient Return Distribution
Wildfire (hot, long-duration burn)	Continuous	All	Diffuse[a]	Mineral, black carbon	Concentrated and diffuse
Selective logging	Patchy	Woody	Linear and patches	Unprocessed and processed, organic	Depends on management of logging slash
Grazing (moderate)	Patchy	Herbaceous	Linear and patches	Mineral and processed organic	Discrete, concentrated (dung), diffuse (trampled vegetation)
Vehicle traffic (off-road)	Corridors	All within wheel tracks	Linear	Negligible within track	Negligible

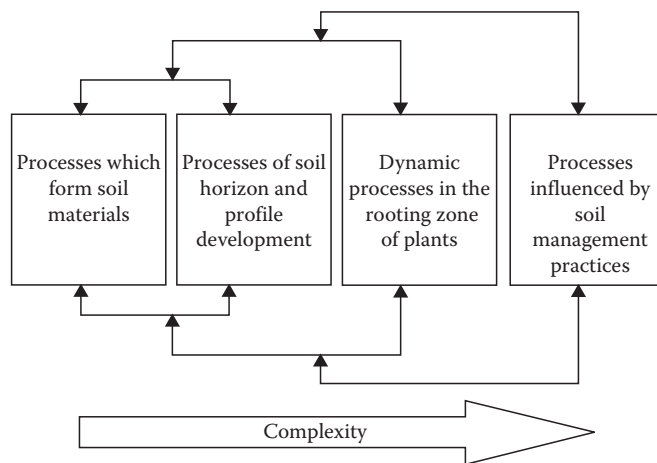
[a] The effect here is indirect and maybe delayed: Fire may increase soil hydrophobicity, crusting, and compaction by removing protective vegetation and litter layers.


FIGURE 38.1 Processes involved in soil change. Soil systems function through many interacting processes. (Modified from Ross, S. 1989. Soil processes: A systematic approach. Routledge, London, U.K.)

(2) processes of soil horizon and profile development, (3) dynamic processes in the rooting zone of plants, and (4) processes influenced by management practices (Figure 38.1). Acknowledging that probably no soil process is uniquely biogeochemical, pedogenic, ecological, or geomorphic, it is important to draw upon many disciplines in our efforts to understand soil change. In the Anthropocene, it is important to join these traditions to enrich and broaden perspectives of soil and what has recently been called Earth's critical zone (National Research Council, 2001; Richter and Mobley, 2009). Pedology may focus on processes that alter soil material, geo- and biogeochemistry on chemical reactions, and ecology on system interactions, but the system is the same and the needs for understanding changes in the system justify a more integrated critical zone science (Wilding and Lin, 2006). The four primary processes of additions, losses, transformations, and translocations, originally formulated by the pedologist, Simonson (1959), are biogeochemical and ecological processes discussed in detail by Chadwick and Graham (2000)

and Richter and Markewitz (2001). Distinctions between disciplines become blurred when considering biologically mediated processes such as the physical-displacement forces applied to soil by growing roots (Brimhall et al., 1991; Richter et al., 2007) or porosity-dependent, acid-induced transformations and weathering of soil minerals affected by soil microbes and plant respiration (Richter and Markewitz, 1995).

Processes related to forcing factors and plant growth are a primary focus in disciplines such as agronomy and silviculture, as well as the sciences of desertification and land degradation. Land use conversions and agricultural practices can quickly alter existing soil processes and even introduce new processes to the soil system (Ross, 1989). The alteration of soil physical and chemical properties and processes through plowing, drainage, and additions of new materials alter soil physical, chemical, and biological processes and primarily affect (1) soil structure, (2) porosity, (3) soil moisture and temperature dynamics, (4) heat flux, (5) soil trafficability and workability, and (6) nutrient storage and release. Tillage may control weeds, but it may also break down soil aggregates and promote soil compaction, processes that have generally negative consequences to hydrologic soil function and nutrient cycling.

Studies of soil and land degradation and desertification are concerned with processes that substantially decrease an area's biological productivity or usefulness to humanity. Soil degradation itself is defined as "a process that describes human-induced phenomena, which lower the current and/or future capacity of the soil to support human life" (Oldeman and van Lynden, 1997). Water erosion, wind erosion, salinization, and chemical, physical, and biological deterioration are among the many soil degradation processes enumerated in the literature and of grave concern with respect to the production of goods and services. The set of processes mapped in the Global Assessment of the Status of Human-induced Soil Degradation, while commonly cited, is not comprehensive and is limited to those processes occurring across extensive areas of the world (Oldeman et al., 1991; Chen et al., 2002; Lal et al., 2004).

Synthesis of process information from a wide range of disciplines is essential to understand and predict human impacts on soil systems over time. Palm et al. (2007) advocate identifying relationships between land management, degradation processes, and impacts of those processes. Positive or negative feedbacks among soils, plants, and animals, the atmosphere and climate, and management can together lead to soil change (Lawrence et al., 2007) and impact the functional capacity of soil at a number of spatial scales (Herrick and Whitford, 1999). Furthermore, a specific land management practice can trigger more than one type of soil degradation process and one type of impact (Stocking, 1995).

38.6.3 Resistance and Resilience

The response of soils to forces and stressors is controlled by soil's ability to absorb, resist, and recover from the forces. The concepts resistance, resilience, and buffering help describe soils' response. Ecological discussion over concepts of resistance and resilience is extensive and vigorous (Holling, 1973; Pimm, 1984; Gunderson, 2000; Briske et al., 2008; Bestelmeyer et al., 2009a), a discussion that extends to engineering and pedology (Greenland and Szablocs, 1994; Holling, 1996). From perspective of the soil, resistance is the capacity to maintain functional capacity through disturbances, and resilience is the capacity to recover the functional and structural integrity lost after a disturbance or prolonged stress (Blum, 1997; Seybold et al., 1999). Some concepts of resilience incorporate resistance to change as well as the capacity to recover (Holling, 1973; Szabolcs, 1994; Gunderson, 2000; Tenywa et al., 2006). Quantitative estimates of soil resilience are based on pre- and postconditions and computed using process rates (Szabolcs, 1994), dynamic soil properties (Seybold et al., 1999), or a combination of properties and processes (Lal, 1994). Soil resilience differs somewhat from ecological resilience, as ecological resilience involves multiple subsystems of the ecosystem (e.g., plant community, soil fauna) (Walker et al., 2004). Soil resilience is therefore a component of ecological resilience.

One of the interests in soil resilience is to estimate the possibility of reversing change in soil and soil function. Arnold et al. (1990) offer an approach for estimating reversibility that uses a ratio of rates of change that gives insight to the time frame required for reversal. From a land management perspective, the length of time required to reverse a change can have a significant influence on the perception of the ease of reversibility and its costs. Reversibility is characterized using rate or velocity of change and is classified on the basis of the ratio of the primary change process to the reverse process. If both the primary change and reversal processes are either rapid or slow, the system is considered reversible. This approach also illustrates that the reversal process is often different from the primary change process thus exhibiting pronounced hysteresis.

While few soil changes may be truly irreversible, reverse changes that may prove intractable include severe erosion, salinization without a suitable outlet for drainage water or salts,

drainage and oxidation of sulfidic soil materials (iron pyrite, FeS_2), and heavy metal contamination.

38.7 Spatial and Temporal Patterns of Soil Change: Attributes for Prediction

The ability to predict how soils change over human timescales is critical to the success of sustainable soil management. Dynamic soil properties can be used to document change as well as quantify processes and soil functional capacity. Predicting change and its effect on processes and function requires observational data and models to describe and simulate temporal patterns exhibited by dynamic soil properties. Measuring temporal variation across space, however, as is required in LTSEs, STSEs, and SFTSs, is complicated by inherent and human-induced spatial variability of soil properties. Spatial and temporal variability of dynamic soil properties within systems are treated in this section.

38.7.1 Dynamic Soil Properties

When studying soil change within the Anthropocene, the variables of particular interest are dynamic soil properties (Tugel et al., 2005). Dynamic soil properties include use-dependent properties (Grossman et al., 2001). Many dynamic properties are indicative of soil function (see Chapter 26 of *Handbook of Soil Sciences: Resource Management and Environmental Impacts*) and recently soil survey document attainable levels and change in properties and function (Tugel et al., 2008).

Guidelines for selecting a minimum data set of dynamic soil properties for monitoring and soil survey comparison studies focus on functions of interest as well as ease of measurement, reproducibility, and cost (Larson and Pierce, 1991). Minimum soil-data sets typically will include bulk density, aggregate stability, infiltration, organic matter, pH, EC, exchangeable cations, extractable P, and potentially mineralizable N, which help characterize key soil functions and processes. Biological measures such as microbial biomass-C are also included where time of sampling can be controlled or seasonal fluctuations can be modeled.

In addition to land use and management, dynamic soil properties are affected by changes that are gradual, for example, a slowly warming climate or a prolonged drought, and that are oscillatory, for example, diurnal and seasonal regimes of temperature or moisture (Table 38.5). The dynamic soil properties' sensitivity to diurnal and seasonal environmental fluctuations may vary greatly and should be considered when selecting properties for inclusion in a study, especially SFTSs and LTRMs where seasonal measurements are not likely to be made. Repeated observations of properties sensitive to environmental fluctuations can be misinterpreted as management-related differences unless they are measured at the same time of day (diurnal sensitivity) or year (seasonal sensitivity). Environmental fluctuations

TABLE 38.5 Sensitivity of Soil Properties to Environmental Fluctuation in Temperature and Moisture

Sensitivity	
Diurnal	Seasonal
Soil temperature	Soil temperature
Composition of soil air	Moisture content
Redox potential	Bulk density, total porosity
	Aggregate stability
	Infiltration rate, hydraulic conductivity
	Bioavailability of macro- and micronutrients
	Microbial activity
	Electrical conductivity
	pH
	Redoximorphic features

Many soil properties respond to environmentally induced fluctuations in temperature and moisture. The environmental sensitivity should be considered when designing a study to ensure selection of suitable properties and the proper timing and frequency of measurement.

and anticipated changes in trends should be considered when designing a study to ensure proper selection of suitable properties, timing and frequency of measurement, and overall duration of study.

38.7.2 Spatial Patterns

The spatial variability of dynamic soil properties depends upon the type of soil, the plant community, the scale of disturbance, and the management history as well as the scale of measurement (Wilding et al., 1994). Legacies from past land use and management can persist in modern systems, such as tillage-related decreases in soil organic matter, contributing to spatial variability of dynamic soil properties (Foster et al., 2003; McLauchlan, 2006; Li et al., 2010). Understanding legacies and historic ranges of anthropogenic and nonanthropogenic variability is essential in interpreting modern changes in soil, although this knowledge does not include all of the information necessary for predicting future change (Millar and Woolfenden, 1999; Parsons et al., 1999).

The spatial variability of dynamic soil properties is often associated with spatial patterns of vegetation or local terrain, such as coppiced shrubs and concave intershrub spaces. Information about these patterns is important for the prediction of soil change and its effects on function. An example includes rows and furrows within a field and their effect on (1) salt redistribution within the soil after irrigation and (2) toxic salt damage to the crop (Wadleigh and Fireman, 1949; Miyamoto and Cruz, 1987; Ashraf and Saeed, 2006).

38.7.3 Temporal Patterns

Timescales over which dynamic soil properties change in response to land use and management vary from minutes to hundreds of years or more (Sparling, 2006; Richter, 2007).

Fluctuation, trend, rate, pathway of change, feedback, hysteresis, thresholds, and fluxes are used to describe temporal patterns of soil change. Study objectives and the suitability of the various measurement techniques for documenting these attributes should be considered when initiating a project to document change. Detailed descriptions of the following attributes of change are located in Arnold et al. (1990) and Tugel et al. (2008).

38.7.3.1 Fluctuations and Trends

Fluctuation is temporal variation in soil properties and includes nonsystematic, random variation and regular periodic, cyclic variation.

Trend is the general direction of change and can be increasing, decreasing, or steady-state equilibrium. The time it takes to approach or a dynamic equilibrium varies with the property, the kind of soil, the type of management, and any continuing forcing factors.

38.7.3.2 Rate, Pathways of Change, and Feedbacks

Rates of soil change are rarely constant. Temporal variation in dynamic soil properties can follow pathways that are logistic or exponential and are uncommonly linear, owing to fluctuations and feedbacks. Feedback mechanisms are involved when the rate changes. Positive feedbacks intensify process rates, and negative feedbacks diminish or limit rates. Where feedbacks accelerate process rates, such as increasing rates of surface runoff and erosion over time, the feedback is positive, though the result may have a negative effect on soil function. Plant–soil feedbacks have been suggested to be strongest for plants growing in extreme environments (Ehrenfeld et al., 2005).

38.7.3.3 Thresholds

Thresholds in soils are tipping points and have application to many processes (Chadwick and Chorover, 2001). In ecosystem management, an ecological threshold represents the conditions at a point in time after which future management options become limited and corresponds to the shift from one alternative state to another (Hobbs and Harris, 2001; Bestelmeyer, 2006; Bestelmeyer et al., 2009b). Recognition of a threshold implies that a functionally important change in process rate has occurred.

38.7.3.4 Fluxes

Fluxes in soils can be energetic or material and occur via the gas, liquid, or solid phases. The importance of fluxes is underscored by Simonson's (1959) classical view of the processes of pedogenesis in which three of four of Simonson's general processes involved material and energy fluxes: inputs, removals, and translocations. Fluxes are measured as the rate of movement of chemical elements, or materials such as organic matter, clay minerals, or colloids. Fluxes are key to the functioning of the internal soil system and to how and why soil interacts with the wider environment. Much about soil management, in the past and in the future, involves the management of energetic and material fluxes.

Examples of how inputs, removals, and translocations have altered soils are far too few. The best examples of research and management sites that link changes in soil systems with fluxes of materials into, through, and out of the soil over decadal timescales are long-term soil experiments (Richter et al., 2007).

38.7.4 Reorganization in Space and Time

Changes in process rates, feedbacks, and thresholds are involved in pattern reorganization within systems. Because dynamic soil properties reflect processes, property–process–pattern relationships can be established. Furthermore, spatial patterns of soil properties and plant communities can shift and reorganize through time in response to stressors, disturbances, and vegetation dynamics (Bestelmeyer et al., 2006; Ravi et al., 2010).

Awareness of property–process–pattern reorganization is essential for prediction of future changes. In one example (Figure 38.2), heavy continuous grazing followed by drought may produce positive feedbacks between vegetation and soil properties that intensify physical, chemical, and biological degradation. The feedbacks lead to the following: (a) a decrease in soil organic matter and an increase in size of bare spaces, (b) a decrease in soil aggregate stability and reduced resistance to erosion, (c) a loss of topsoil through erosion and a decrease in infiltration, and (d) an additional loss of grass and increase in shrubs, which cause the feedback loop to continue (Bird et al., 2001). Eventually, a system will reach and cross a threshold to a new state with altered properties, processes, and patterns.

Of concern to sustained land and environmental management are postthreshold conditions such as reduced acid buffering capacity, impaired hydrologic processes, displaced plant communities, or different crop suitabilities when compared to the prethreshold states (Groffman et al., 2006). The management actions used to restore a postthreshold state may be different and more costly than those used to keep a system from crossing a threshold (Stringham et al., 2003). Once a threshold has been crossed, the limited reversibility of the resulting conditions may restrict future management options.

38.8 The Science and Management of Soil Change: Status and Future

About half of the approximately 13 billion ha of Earth's soil are now managed for human use: cultivated for crops; managed for pastures and hayfields; logged for wood; disturbed by mining; developed for urban, suburban, transportation, industrial, and recreational projects; and used to process burgeoning streams of human and animal wastes (FAO-STAT, 2009). Important areas are contaminated by chemical compounds and large areas lie in wait of conversion for use or reuse in the coming decades. All of these soils are also being affected by changing climates and increasing concentrations of atmospheric CO_2 and other greenhouse gases. The age of pedogenesis has given way to the age of anthropedogenesis.

Sustainably managing this change so that future management and soil function are not compromised is a goal well-worth bequesting to future generations. Creating this legacy is entirely contingent upon our ability to predict and improve management of soil change on the human timescale. Land managers and policy analysts need new soil survey products that provide information about soil's resistance to stress and disturbance, soil's ability to recover readily (resilience), and any prethreshold

FIGURE 38.2 Effects of management on reorganization of soil property–process–pattern. Interactions between plant and soils contribute to the reorganization. Decreases in organic matter, aggregate stability, and resistance to erosion occur are associated with bare spaces that can continue to expand as degradation proceeds. (Modified from Bird, S.B., J.E. Herrick, and M.M. Wander. 2001. Exploiting heterogeneity of soil organic matter in rangelands: Benefits for carbon sequestration, p. 121–138. *In* R.J. Follett, J.M. Kimble, and R. Lal (eds.) The potential of U.S. grazing lands to sequester carbon and mitigate the greenhouse effect. CRC Press LLC, Boca Raton, FL.)

indices that warn about the loss of soil function. At present, our understanding of how soils are changing over decades' time and the potential prolonged effects of these changes on soil function can only be described as elementary (Richter and Markewitz, 2001; Tugel et al., 2005). Pedology and anthropedology must advance an interdisciplinary science of Earth's soil, that is, Earth's critical zone (National Research Council, 2001) in order to provide the foundation for long-term sustained soil and landscape management.

Pedologists in the Anthropocene (i.e., anthropedologists) use a science that is both basic and applied and has ever increasing interdisciplinary requirements to address sustainability and management challenges. Anthropedology must focus on management resilience of soils to help increase the production of goods and services without forcing systems across thresholds to undesired or difficult-to-reverse states (Bestelmeyer et al., 2009a). We suggest that improved management requires future soils research in five areas:

1. Pedogenic processes in human-altered systems
2. Soil changes and effects on functions and potentials for use
3. Mechanisms involved in soil change, degradation, and recovery
4. Prethreshold indices to predict difficult-to-reverse soil conditions
5. Restoration of highly degraded soil

The battery of approaches described in this chapter (LTSEs, STSEs, SFTSs, LTRM's, and models) can quantify soil change and improve sustainability of soil management. Many disciplines from the sciences and humanities will be needed for successful quantification and interpretation of humanity's effect on soil function.

Contemporary pedologists need to focus on the human element as a factor driving soil formation and transformation in the Anthropocene. It is humanity's transformation of Earth's soil that challenges scientists to develop a pedology with broad purview and decades' to centuries' timescales, and a pedology that supports the science, inventory, and management of the environment, ecosystems, and global change.

Noninvasive Geophysical Methods Used in Soil Science

James A. Doolittle
*United States Department
of Agriculture*

39.1 Introduction

Geophysical methods measure changes in some physical property (i.e., density, seismic velocity, electrical conductivity, electrical resistivity [ER], magnetic susceptibility, dielectric permittivity) of the subsurface without direct access to the sampled volume (Daniels et al., 2003; Allred et al., 2008). Over the last three decades, the use of geophysical methods has significantly increased in soil investigations. The geophysical methods most commonly used in these pursuits include electromagnetic induction (EMI), ground-penetrating radar (GPR), transient EMI, galvanic resistivity, and magnetics. These methods are used to infer and better understand the spatial variability of soils and soil properties, and to guide observations and sampling. Selection of the most suitable geophysical method often requires an understanding of the soil properties that influence the method's response, and whether, and to what extent, a selected soil property affects the measured physical property (Allred et al., 2008). Whereas surface geophysical methods allow more continuous coverage than traditional approaches, they are limited in their capacity to resolve and characterize many pedologic features. Recent improvements in instrumentation and the integration of geophysical methods with other technologies (global positioning systems [GPS], data processing software, and surface mapping programs; e.g., geographic information systems [GIS], Geosoft, and Surfer) have fostered the expanded use of geophysical methods in soil investigations. The impetus has been the needs to improve quality control, provide more comprehensive coverage, and increase the efficiency of field operations. In agriculture, the three most commonly used geophysical methods are EMI, GPR, and Electrical resistivity (Allred et al., 2008). This chapter will focus on two of these geophysical methods: GPR and EMI. The initial uses, expansion, and present-day applications of GPR and EMI in agriculture have been summarized by Collins (2008) and Corwin (2008), respectively. As numbers of applications have become diverse and numerous, with a considerable amount of literature written on the uses of these geophysical methods in soil science, it is impossible for this brief discussion to cover all of these applications and papers.

39.2 Ground-Penetrating Radar

39.2.1 System Overview

39.2.1.1 Principles of Operation

Ground-penetrating radar is an impulse radar system designed for shallow (0–30 m) subsurface investigations. GPR systems transmit short pulses of very-high- and ultrahigh-frequency (from about 30 MHz to 1.2 GHz) electromagnetic energy into the ground from an antenna. Each pulse consists of a spectrum of frequencies distributed around the center frequency of the transmitting antenna. The transmitted pulses of energy are propagated downward into the soil. Whenever this wave of energy contacts an interface that separates layers with different permittivity (e.g., boundaries separating major soil, stratigraphic, and lithologic layers or features), a portion of this energy is reflected back to a receiving antenna. The more abrupt and contrasting the permittivity on opposing sides of an interface, the greater the amount of energy that is reflected back to the antenna. The receiving unit amplifies and samples the reflected energy and converts it into a similarly shaped waveform in a lower frequency range. The processed reflected waveforms are displayed on a video screen and can be stored on a hard disk for future playback and/or processing.

Ground-penetrating radar is a time scaled system. This system measures the time that it takes electromagnetic energy to travel from an antenna to a subsurface interface and back. To convert the travel time into a depth scale, the velocity of pulse propagation or the depth to a reflector must be known. The relationships among depth (*D*), two-way pulse travel time (*T*), and velocity of propagation (*v*) are described in the following equation (after Daniels, 2004):

$$v = 2\frac{D}{T}. \tag{39.1}$$

The velocity of propagation is principally affected by the relative permittivity (*E*$_r$) of the profiled material(s) according to the equation (after Daniels, 2004):

$$E_r = \left(\frac{C}{v}\right)^2. \tag{39.2}$$

In Equation 39.2, *C* is the velocity of light in a vacuum (0.3 m ns^{-1}). Velocity is often expressed in meters per nanosecond (m ns^{-1}).

Relative permittivity is a dimensionless constant that describes a material's capacity to store and release electromagnetic energy in the form of an electrical charge (Cassidy, 2009). Relative permittivity is expressed as (after Cassidy, 2009)

$$E_r = \frac{(E)}{(E_0)}. \tag{39.3}$$

where

E is the permittivity of the material
E$_0$ is the permittivity of free space (8.8542 × 10^{-12})

The relative permittivity varies with the amount of free and bound water (Cassidy, 2009). Relative permittivity ranges from 1 for air to 78–88 for water (Cassidy, 2009). Small increments in soil moisture can result in substantial increases in the relative permittivity of soils (Daniels, 2004). Using a 100 MHz antenna, Daniels (2004) observed that the relative permittivity of most dry mineral soil materials is between 2 and 10, while for most wet mineral soil materials, it is between 10 and 30. The relative permittivity of saturated peat deposits can range from 43 to 69 (Ulriksen, 1982). The relative dielectric permittivity of permafrost ranges from 2 to 8 (Cassidy, 2009). It should be noted that these reported values are simply approximations that were derived largely from laboratory experiments rather than real-world experiences (Cassidy, 2009). There is a tendency for permittivity to decrease with increasing frequency and conductivity to increase with increasing frequency (Annan, 2001).

39.2.1.2 Equipment

A typical GPR system consists of a radar control unit with transmitting and receiving antennas. The control unit consists of a screen, microprocessor, and mass storage medium. A microcomputer is used to control measurement processes, store data, and serve as a user interface. Modern GPR systems are lightweight and highly portable (Figure 39.1). Principal manufacturers of GPR include Geophysical Survey Systems Inc. (GSSI; Salem, New Hampshire); MALÅ (Stockholm, Sweden); and Software & Sensors (Mississauga, Ontario).

The most common mode of GPR data acquisition is the reflection profiling mode (Figure 39.1) in which radar waves are transmitted, received, and recorded as the antenna is moved along the soil surface. Transillumination methods are less commonly applied in soil investigations and require boreholes. In this method, the transmitter and receiver are placed and moved through two boreholes placed on opposite sides of the measured medium.

Based on GPR systems design and user preference, data are collected in either a continuous or step mode. The continuous mode involves the unidirectional movement of both transmitting and

(a)   (b)

FIGURE 39.1 Radar traverses being conducted in the continuous mode with a GSSI SIR-3000 system and a 200 MHz antenna (a) and a Software & Sensors Noggin system and a 250 MHz antenna (b).

receiving antennas (usually housed in one container or bound together) along a traverse or grid line (Figure 39.1). This mode is well suited to the rapid collection of data over relatively large areas. In the step mode, transmitting and receiving antennas are placed on the soil surface at a set distance apart (constant offset), a scan or multiple scans are obtained, and the antennas are then moved a short measured distance along the traverse line to repeat the process. This method is rather slow and cumbersome. However, averaging multiple scans collected at each measurement point results in a reduction of background noise.

Multi-offset methods are used with some GPR systems. These methods involve varying the distance between the transmitting and receiving antennas. Multi-offset methods are used to obtain estimates of the radar's velocity of propagation versus depth in the ground (Annan, 2009). Two commonly used multi-offset methods are common midpoint (CMP) and wide-angle reflection and refraction (WARR). In CMP, the distance between the antennas is increased stepwise, while the same midpoint position is maintained between the two antennas. In WARR acquisition, the distance between the two antennas is increased stepwise while the transmitter is maintained at a fixed location.

39.2.1.3 Antennas

Antennas are used to transmit energy, receive energy, or both. The resolution and penetration depth of GPR are determined by the antenna frequency and the electrical properties of earthen materials (Olhoeft, 1998; Daniels, 2004). A major constraint of GPR is the relationships between antenna frequency, penetration depth and resolution; resolution will decrease with decreasing antenna center frequency and with increasing depth of penetration (Buynevich et al., 2009). Higher-frequency (>400 MHz) antennas provide higher resolution, but have less penetration depth than lower frequency antennas (<300 MHz). The antennas most commonly used in soil investigations have center frequencies between 100 and 500 MHz. Lower frequency antennas (100–300 MHz) are commonly used for water table, lithologic, and stratigraphic studies, and for investigations in areas of more conductive and attenuating soil materials. Higher-frequency antennas (400–500 MHz) provide better results in relatively dry, electrically resistive soils. Antennas with frequencies of 900 MHz–1.5 GHz have been used for shallow investigations in some coarser-textured soils. For organic soils, where greater depths of penetration are often desired to profile the organic/mineral soil interface, lower frequency (70–200 MHz) antennas are commonly used.

39.2.1.4 Field Methods

For most GPR soil investigations, a traverse line or small grid is established across the study site. Generally, more information is obtained by using a network of traverse lines that capture the extent and variability of GPR reflections (Buynevich et al., 2009). Typically, reference points are located at uniform intervals along traverse or grid lines. The spacing of these reference points varies with the anticipated complexity of soils and soil properties, and can range from several centimeters to several tens of meters.

The number of reference points depends on the feature of interest and the length of the GPR traverse line.

Typically, for soil survey investigations, an appropriate antenna is moved along the ground surface in the continuous mode (Figure 39.1a). On relatively smooth surfaces that are free of debris or other hindrances, a survey wheel can be attached or the antenna placed in a cart with an odometer wheel (Figure 39.1b). Trigger mechanisms on the survey wheel or cart control the start and stop of data recording and provide reliable distance marks (Buynevich et al., 2009). At uniform distances along the traverse line, the operator or the trigger mechanism impresses a mark on the radar record indicating a reference or distance point.

After reviewing the radar record in the field, soils are cored, described, and sampled at few selected reference points along the traverse line to verify GPR depth measurements and interpretations. Based on these observations, subsurface horizons, contrasting layers, and/or features are identified on radar records. For soil survey investigations, the presence and depth to subsurface horizons or features are used to identify soils on the radar record. Later, during the post-surveying analysis of the radar records, the depths to a soil interface of interest are interpreted and manually or semiautomatically entered into a spreadsheet. Basic statistics and descriptive summaries for each traverse line are developed and presented as survey results.

39.2.1.5 GPS Option

During the 1990s, it was realized that, in order to be more useful, GPR data needed to be integrated with available digital soil data and maps. This has led to the integration of GPR with GPS. As noted by Rial et al. (2005), the accurate positioning of radar data with GPS and its importation into GIS is a goal, which will shortly become a perquisite in GPR investigations. Modules have been developed in newer GPR systems and processing software that permits the georeferencing of GPR data. These modules not only visually georeference the GPR data (GSSI, 2008), but have widened the scope of GPR surveys (Gustafsson, 2007).

With GPS, as the radar is moved across a soil polygon, its position is continuously tracked. The number of potential reference points is determined by the speed of advance and the sampling rate set on the radar unit. During post-surveying analysis of radar data, the position of each radar scan is proportionally adjusted according to the time stamp of the two nearest positions recorded with the GPS receiver.

39.2.1.6 Soil Properties That Influence the Effectiveness and Penetration Depth of GPR

Compared with other geophysical techniques, GPR provides the highest resolution of subsurface features. However, GPR is not appropriate for use on all soils (Doolittle, 1987). There are a number of factors that may increase dissipation of radar energy passing through soils including electrical conductivity, water content, soluble salts, carbonate minerals, and gypsum (Campbell, 1990; Olhoeft, 1998; Daniels, 2004). Soils having high electrical conductivity rapidly attenuate radar energy, restrict penetration depths, and severely limit the effectiveness of GPR.

Radar energy dissipation increases with increasing soil water content (SWC) (Campbell, 1990; Daniels, 2004). When an alternating electrical field is applied, water molecules align their permanent dipole moments parallel to the direction of the applied electrical field (Daniels, 2004). The displacement of bound water molecules results in the loss of energy as heat (Neal, 2004) and storage of electrical field energy. At frequencies above 500 MHz, the absorption of energy by water is the principal mechanism for radar energy loss in soils (Daniels, 2004). Even under very dry conditions, the amount of bound water is sufficient to affect radar energy loss in soils (Daniels, 2004).

Electrical conductivity and energy loss are also affected by the concentration of salts in the soil solution (Curtis, 2001). All soil solutions contain some salts, which act as electrolytes and increase ionic conduction. In semiarid and arid regions, however, accumulations of soluble and sparingly soluble salts of K, Na, Ca, and Mg in soils increase the electrical conductivity of the soil solution and the attenuation of electromagnetic energy (Doolittle and Collins, 1995). Because of their high electrical conductivity, saline (electrical conductivity >4 dS m^{-1}) and sodic (sodium absorption ratio ≥13) soils are considered unsuited to most GPR applications. In saline soils, depending on moisture contents, penetration depths typically range from a few to less than 25 cm (Daniels, 2004; Ben-Dor et al., 2009) and GPR is considered an inappropriate tool.

Mukherjee et al. (2010) observed that the dielectric permittivity and electrical conductivity of karstified limestone increased with increasing porosity. Because of increased signal attenuation in saturated carbonate terrains, GPR penetration depths are restricted (Mukherjee et al., 2010). At similar moisture and clay contents, soils with high CaCO$_3$ equivalent have been reported to reduce the depth of GPR penetration in soils (Grant and Schultz, 1994; Lebron et al., 2004).

Because of their high adsorptive capacity for water and exchangeable cations, the penetration depth of GPR is inversely related to clay content. Olhoeft (1986), using a 100 MHz antenna, observed a penetration depth of about 30 m in clay-free sands. However, the addition of only 5% (by weight) smectitic clays reduced the penetration depth by a factor of 20 (Olhoeft, 1986). Doolittle and Collins (1998) noted that, depending on antenna frequency and the specific conductance of the soil solution, GPR penetration depths range from 5 to 30 m in dry, sandy soils, but average less than 50 cm in wet, clayey soils.

Electrical conductivity and energy loss increase with increasing cation exchange capacity (CEC) of the clay fraction (Saarenketo, 1998). Cations adsorbed to the clay particles provide an alternative pathway for electrical conduction and, therefore, contribute to electromagnetic energy losses (Saarenketo, 1998). Soils with clay fractions dominated by high-CEC clays (e.g., smectite and vermiculite) are more attenuating to GPR than soils with an equivalent percentage of low-CEC clays (e.g., kaolinite, gibbsite, and halloysite). For soils with comparable clay and moisture contents, greater depths of penetration can be achieved in highly weathered soils of tropical and subtropical regions than in soils of temperate regions. Additionally, the contribution of clay and surface conduction to electrical conductivity and electromagnetic energy loss is more noticeable in soils that have low concentrations of soluble salts (Klein and Santamarina, 2003).

39.3 GPR Soil Suitability Maps

Knowledge of anticipated depths of penetration is important for the effective use of GPR. Most radar users have limited knowledge of soils and are unable to predict the likely penetration depths or the relative suitability of soils for GPR within study sites. In many soils, high rates of signal attenuation severely restrict penetration depths and limit the suitability of GPR for a large number of applications. In saline and alkali (or sodic) soils, where penetration depths are typically less than 25 cm (Daniels, 2004), GPR is unsuited for most applications. In wet clays, where penetration depths are typically less than 50–100 cm (Doolittle et al., 2003), GPR has very low potential for most applications. However, GPR is highly suited to most applications in dry sands, where penetration depths can exceed 50 m with low frequency antennas (Smith and Jol, 1995).

A map of effective ground conductivity (Fine, 1954) provided broad guidance on anticipated rates of signal attenuation, GPR penetration depths, and the relative suitability of soils to GPR applications within the United States. Because this map was prepared at a small scale (1:2,500,000) and from a limited sample population, resolution was poor and data were generalized, which resulted in many discrepancies between predicted and actual usefulness of GPR at specific sites.

Collins (1992) developed a GPR suitability rating and created GPR suitability maps based on soil classification and soil properties within the upper 2 m. Doolittle et al. (1998) used the USDA–Natural Resources Conservation Services (NRCS) State Soil Geographic (STATSGO) database to create maps that summarized the distribution of several soil properties affecting GPR suitability. Subsequently, these general soil spatial and attribute data were used to develop and later revise the GPR Soil Suitability Map of the Conterminous United States (GSSM-USA) (Figure 39.2; Doolittle et al., 2002b, 2003, 2007), which was based on a larger sample population and offered greater detail than the effective ground conductivity map (Fine, 1954).

Soil attributes used to determine the GPR suitability indices of soil polygons shown on the GSSM-USA include taxonomic criteria, clay content and mineralogy, electrical conductivity, sodium absorption ratio, and CaCO$_3$ and CaSO$_4$ contents. Each soil attribute for each horizon is rated and assigned an index value ranging from 1 to 6. Lower index values are associated with lower rates of signal attenuation and greater penetration depths. For each soil attribute, the most limiting index value within 2 m for each soil in the map unit is selected, and these limiting indices are summed for each soil (the component index value). For each soil map unit, the relative area of soils with the same index values is summed, and the GPR suitability index (GSI) for the soil map unit is the most aerially extensive index value in the map unit.

FIGURE 39.2 **(See color insert.)** The GSSM-USA.

Soil attribute index values and relative soil suitability indices are based on observed responses from antennas with center frequencies between 100 and 200 MHz. For mineral soils, the inferred suitability indices are based on unsaturated conditions and the absence of unpredicted, contrasting soil properties within 2 m. Within any map delineation, the actual performance of GPR will depend on variations in soil properties, the type of application, and the characteristics of the subsurface target. Penetration depths and the relative suitability of soils will be less under saturated conditions, and if shallow groundwater is present, GPR penetration will be reduced and contingent on the ions present in solution.

According to GSSM-USA, only 22% of the soils in the conterminous United States are considered well suited to GPR. Areas of moderate and low potential soils for GPR applications are more extensive and occupy an estimated 33% and 36% of the acreage, respectively. Because of saline and alkaline conditions, 7% of the soils in the conterminous United States are considered unsuited to GPR. As evident from this data, a majority of the soils in the conterminous United States are not well suited for GPR soil investigations, and most successful applications of GPR in the United States has been restricted to regions that have extensive areas of soils that are well suited to GPR.

Because of the small compilation scale (1:250,000) of GSSM-USA, the minimum polygon size is about 625 ha. Larger scale GPR soil suitability maps have been prepared on a state basis

using the USDA–NRCS's Soil Survey Geographic (SSURGO) database (Doolittle et al., 2006b), which is directly derived from soil surveys completed at scales ranging from 1:12,000 to 1:63,360 (minimum delineation size ranging from about 0.6 to 16.2 ha, respectively) (Soil Survey Division Staff, 1993). The same soil properties, attribute index values, and aggregation methods used to prepare GSSM-USA were used to derive these larger scale maps.

An example of these large scale maps, the GPR Soil Suitability Map of Nebraska (GPRSSM-NE), is shown in Figure 39.3. Compared with GSSM-USA (Figure 39.2), soil information contained on GPRSSM-NE (Figure 39.3) is less generalized, soil patterns are more intricate, and polygons are shown with greater resolution. Broad spatial patterns, which correspond to major soil and physiographic units within Nebraska, are evident on both maps (Figures 39.2 and 39.3). However, GPRSSM-NE provides a more detailed overview of the spatial distribution of soil properties that influence the depth of penetration and effectiveness of GPR.

The spatial information contained on GPR soil suitability maps can aid evaluations of the relative appropriateness of using GPR, selection of the most suitable antennas and survey procedures, and the need and level of data processing. GPR soil suitability maps are available for most states and can be accessed at http://soils.usda.gov/survey/geography/maps/GPR/index.html. These maps are periodically updated as additional soil information is collected and certified.

39.3.1 Factors Influencing Feature Detection

39.3.1.1 Reflection Coefficient

The amount of energy reflected back to an antenna is a function of the dielectric gradient that exists across a soil interface or boundary. The greater and more abrupt the contrast in the dielectric properties of adjoining soil materials, the greater the amount of energy reflected back to the antenna, and the more intense and conspicuous the amplitude of the reflected signal appearing on radar records. Soil horizons, layers, and features that have similar relative permittivity are poor reflectors of electromagnetic energy and are difficult to identify on radar records. The reflection coefficient, R, is a measure used to express the difference in relative permittivity that exists between two adjoining materials. The reflection coefficient is proportional to reflection strength and is expressed as (after Neal, 2004)

$$R = \frac{\sqrt{E_{r2}} - \sqrt{E_{r1}}}{\sqrt{E_{r2}} + \sqrt{E_{r1}}}, \qquad (39.4)$$

where E_{r1} and E_{r2} are the relative permittivity of adjoining materials 1 and 2. As evident in Equation 39.4, R is dependent on the difference in the relative permittivity between the two adjoining materials.

The E_r values of most dry and wet, mineral soil materials range from 2 to 10 and from 10 to 30, respectively (Daniels, 2004). The E_r of soil materials is strongly dependent upon moisture content,

and the amount of energy reflected back to the radar's antenna is greatly influenced by the abruptness and difference in moisture content between soil horizons, layers, or features.

Typically, strong radar reflections (high-amplitude reflections) are produced by abrupt soil interfaces that separate contrasting soil materials and often correspond to boundaries between soil horizons. Differences between horizons that result in high-amplitude reflections commonly are associated with differences in moisture contents, physical (grain size, texture, bulk density), and/or chemical (organic carbon, calcium carbonate, sesquioxides) properties of the horizons. GPR has been used to determine the depth to bedrock, contrasting master (E, B, C, and R) horizons, buried genetic horizons, frozen soil layers, illuvial accumulations of clays or organic matter, and cemented or indurated horizons. GPR does not detect subtle changes in soil properties (e.g., color, mottles, structure, porosity, slight changes in texture), transitional horizons (e.g., AB, AC, BC), or most vertical divisions in master horizons.

GPR does not directly measure the water table depth, but responds to near-saturated conditions within or near the top of the capillary fringe associated with a water table (Smith et al., 1992; Bentley and Trenholm, 2002). As the width of the capillary fringe above a water table increases, reflections from the water table have increasingly lower amplitudes, more dispersed characteristics and are, therefore, less distinguishable on radar records (Annan et al., 1991). In coarse-textured soils, the capillary fringe is narrow, the difference in permittivity

between the unsaturated and saturated zones is abrupt and contrasting, and the water table is often distinguishable on radar records. The more gradual change in water content over greater distance in clayey soils results in less distinct radar reflections.

39.3.1.2 Resolution

Resolution is the ability to detect two closely spaced interfaces or distinguish a subsurface feature. In order to be resolved, the thickness of a layer must be at least the same dimension as the wavelength, or the travel time through the layer must be equal to or greater than the pulse duration (Annan, 2001). Horizontal or lateral resolution depends on the velocity of propagation, the antenna's bandwidth, and the distance from the antenna. As radar waves propagate through the soil, they expand to form a conical "footprint" area. Consequently, the more distant a layer or feature is from the antenna, the wider the footprint area and the lower the horizontal resolution (Annan, 2001). Higher-frequency antennas have larger bandwidths and therefore provide greater horizontal resolution than lower frequency antennas (Annan, 2009).

The vertical resolution is dependent on the propagated wavelength (λ), which is determined by dividing the propagation velocity (v) by the antenna frequency (f) (after Daniels, 2004):

$$\lambda = \frac{v}{f}. \qquad (39.5)$$

In general, vertical resolution is considered to be about one-fourth the wavelength of the radar signal. If two features are separated in time by less than this amount, they will be indistinguishable on radar records and interpreted as one. However, as noted by Moorman and Michel (1997), the detection limit is considerably lower than the theoretical vertical resolution. Annan (2009) observed that two features must be separated in time by at least one-half of the wavelength to be identified. As can be seen in Equation 39.5, lower frequency antennas have longer wavelengths and therefore afford lower vertical resolution than higher-frequency antennas.

39.3.1.3 Scattering losses

Scattering losses are frequency dependent and become significant at high radar frequencies (Annan, 2009). Scattering is necessary for the detection of major interfaces or features. However, excessive scattering, caused by small-scale heterogeneities or scattering bodies (e.g., rock fragments, tree roots, animal burrows, and cultural features or debris) in the soil, results in unwanted background noise that impairs interpretations. Large numbers of scattering bodies confound interpretations by producing numerous, undesired, subsurface reflections, which clutter radar records and mask or obscure the signal from soil features of interest. Additionally, scattering losses may be the most significant source of signal attenuation restricting penetration depths (Annan, 2001).

39.3.2 Display and Interpretation

39.3.2.1 Two-Dimensional Display

Radar records are similar in appearance to sonar or seismic-reflection profiles. By moving an antenna along the soil surface, a large number of radar scans (or traces) are recorded at a fixed rate or intervals (time or distance) producing a 2D radar record. On 2D radar records, the horizontal scale is distance, which is based on the rate of antenna advance or the distance traveled. The vertical scale is based on the round-trip travel time of the electromagnetic wave. Radar records are displayed as either line-scan or wiggle-trace displays (Figure 39.4b and a, respectively). Wiggle traces are preferred by most engineers and geologists who are familiar with oscilloscope displays. Line-scan displays assign colors or color intensity to the amplitude range on the traces. Line-scan displays are most frequently used for GPR data because of the high data volume (number of traces) (Daniels et al., 2008).

Figure 39.4 contains two displays of the same 2D radar record, which was collected in an area of Bridgehampton soil (coarse-silty, mixed, active, mesic Typic Dystrudepts) in Rhode Island. Bridgehampton soils formed in thick, silty aeolian deposits that are underlain by stratified sands and gravels. In Figure 39.4, the horizontal scale is expressed in meters and is based on measured distances along the traverse line. The vertical scale is based on a velocity of propagation that was determined by comparing the measured depth of a feature with the two-way travel time to the subsurface interface (e.g., the contact of the silty aeolian mantle with the underlying coarse-textured outwash) and Equation 39.1. In the renditions shown in Figure 39.4, the aeolian mantle is virtually free of reflectors. The uppermost, high-amplitude subsurface reflector represents the aeolian mantle/outwash interface. The underlying outwash is characterized by linear reflectors of varying amplitudes. In the two renditions of this 2D radar record, the aeolian mantle/outwash interface is punctuated by an incised feature (between the 6 and 8 m distance marks) whose form and expression suggests an ice-wedge cast.

39.3.2.2 Three-Dimensional Display

The effective visualization of radar data is the key to modern GPR interpretations. An emerging approach in GPR is the analysis of subsurface structures and geometries from a 3D perspective. Three-dimensional GPR allows the visualization of data volumes from different perspectives and cross sections (Beres et al., 1999), which can assist identification, characterize subsurface soil, stratigraphic and lithologic structures and geometries, and improve interpretations of subsurface features. In areas of electrically resistive materials, 3D GPR can provide unrivaled resolution and detail of subsurface features as compared with 2D GPR (Grasmueck and Green, 1996). The use of 3D GPR has allowed improved definition of subsurface features and resulted in more complete and less ambiguous interpretations than traditional 2D GPR (Beres et al., 1999).

The acquisition of data for 3D GPR requires greater expenditures of time and labor than 2D GPR. However, the additional expenditures of resources needed to collect, process, and visualize
(a)

(b)

FIGURE 39.4 Two examples of the same 2D radar record, which was collected with a 200 MHz antenna in an area of Bridgehampton soils. The radar record is displayed as a (a) wiggle-trace and (b) a line-scan display.

3D GPR data are often compensated by the more comprehensive spatial coverage and greater resolution of subsurface features (Grasmueck and Green, 1996). Important considerations for collecting and interpreting 3D GPR surveys are discussed by Lehmann and Green (1999). The basic process to construct a 3D GPR pseudo-images of the subsurface is that a relatively small area (typically, 1–2500 m²) is intensively surveyed with multiple, closely spaced (typically, 0.1–1.0 m), parallel GPR traverse lines. This relatively dense set of grid lines is necessary to resolve the geometries and sizes of different subsurface features and to minimize spatially aliasing the data (Grasmueck and Green, 1996). Appropriate computer software allows the 3D GPR pseudo-image to be viewed from nearly any perspective (Junck and Jol, 2000) and arbitrary cross sections, insets, and time slices can be extracted from the 3D data set. In addition, animated imaging capability allows users to interactively examine the entire data volume (Grasmueck, 1996).

Three-dimensional GPR has been used to identify the presence and map the geometries of subsurface features in both consolidated and unconsolidated materials. Recently, 3D GPR was used to investigate the subsurface configuration of ice-wedge polygons near Barrow, Alaska (Munroe et al., 2007), and sediment filled wedges and buried polygonal ground in mid-latitude United States (Doolittle and Nelson, 2009).

Figure 39.5 contains a 2D radar record and two 3D GPR pseudo-images from a small (30 × 30 m) grid site located in an area of Delton soils (loamy, mixed, active, mesic Arenic Hapludalfs) in Wisconsin. Delton soils formed in a thin (50–100 cm) mantle of aeolian sands overlying clayey lacustrine deposits. On the 2D radar record (Figure 39.5a), the topography of the contact between the aeolian sands and underlying lacustrine deposits (highlighted with a segmented, line) appears wavy with two conspicuous concavities. On the two 3D GPR pseudo-images, a solid cube (Figure 39.5b) and a cube with a 23 × 29 m inset removed to a depth of 100 cm (Figure 39.5c) are shown. Along the sidewalls of the solid 3D GPR pseudo-image, the interface separating the sandy aeolian mantle from the underlying clayey lacustrine deposits is clearly expressed. The 3D GPR pseudo-image with the inset cube removed shows a series of linear and intersecting, high-amplitude (colored white) reflections on the base of the cutout cube. The geometry of these reflectors suggests buried polygonal ground created in a former periglacial environment. Closed segments in the lineations resulted from finer
FIGURE 39.5 A 2D radar record and 3D GPR pseudo-images from a 30 × 30 m grid site in Wisconsin. (a) The segmented line in the 2D radar record shows the contact separating a sand mantle from the underlying clayey lacustrine deposits. (b and c). The 3D pseudo-images show the geometry of the ice-wedge pseudomorphs. (From Doolittle, J.A., and F.E. Nelson. 2009. Characterizing relict cryogenic macrostructures in mid-latitude areas of the USA with three-dimensional ground-penetrating radar. Permafrost Periglac. Process. 20:257–268.)

textured, more radar opaque material filling the ice-wedge voids. These closed segments were interpreted to have formed as portions of the finer-textured, ice-rich lacustrine deposits, which were susceptible to consolidation and deformation, closed during thawing and prevented infilling with superjacent sands.

39.3.3 Applications

39.3.3.1 Use of GPR in Soil Survey

Ground-penetrating radar provides data on the presence, depth, lateral extent, and variability of many diagnostic subsurface horizons that are used to classify soils (Collins et al., 1986; Doolittle, 1987; Schellentrager et al., 1988; Puckett et al., 1990). In the United States, GPR is principally used as a quality control tool to verify the taxonomic composition of soil map units, document the presence and depth to soil horizons and features, and assess spatial and temporal variations in soil properties.

GPR was first used in Florida in 1979 to identify and determine depths to diagnostic subsurface horizons used to classify and map soils (Benson and Glaccum, 1979; Johnson et al., 1979; Collins, 2008). Since that time, GPR has been used extensively for soil survey quality control in Florida because of the ubiquity of sandy soils with favorable physiochemical properties for electromagnetic wave propagation and the presence of contrasting soil horizons (Schellentrager et al., 1988).

Johnson et al. (1979) working in sandy soils with well-expressed horizons, observed that radar interpreted depths of selected horizon boundaries were within ±2.5–5.0 cm of the measured depths. Asmussen et al. (1986) observed an average difference of 19.2 cm between the radar interpreted and measured depths to argillic (Bt) horizons, which ranged in depth from about 20 to 450 cm. Rebertus et al. (1989) observed that the difference between the interpreted and measured depths to a discontinuity, which ranged in depth from 0 to about 230 cm, was less than 15 cm in 94% of the observations. Collins et al. (1989) observed an average difference of 6 cm between the interpreted and measured depths to bedrock, which ranged in depth from about 80 to 240 cm. Simeoni et al. (2009) reported an accuracy of ±10 cm between the interpreted and measured depths to B horizon, which ranged in depth from about 25 to 100 cm. For organic soils, Rosa et al. (2008) reported a mean maximum difference of 32 cm between measured and GPR interpreted depths of peat, which ranged in thickness from 0 to 8 m. Differences were attributed to surface and subsurface irregularities, and spatial variations in peat moisture contents and bulk densities (Rosa et al., 2008).

In a GPR evaluation of Fuquay soils (loamy, kaolinitic, thermic Arenic Plinthic Kandiudults) in northern Florida, the sandy mantle overlying loamy marine deposits is virtually free of reflectors (Figure 39.6). The underlying, loamy sediments, though relatively transparent to GPR, contain a large number
(a)   (b)

FIGURE 39.6 Radar record (b) showing contact of sandy deposits with the underlying, more heterogeneous, loamy marine sediments from an area of Fuquay soils (a) in Florida.

of reflectors, which aid identification of the contact between the two materials. The large number of reflectors of varying sizes, shapes, orientations, and reflected signal amplitudes suggests heterogeneous soil materials, which may be alternating layers of loamy and sandy materials with pockets of ironstone nodules that are evident in the lower part of the Fuquay photograph (Figure 39.6a). As over 1 m of penetration was achieved with the 200 MHz antenna through these loamy materials, the clay fraction is assumed to be dominated by low-activity clay minerals (e.g., kaolinite, gibbsite, and goethite) as implied in the taxonomic classifications of Fuquay soils (Kandiudults).

Ground-penetrating radar has been used to estimate the depth to argillic horizons (Asmussen et al., 1986; Collins and Doolittle, 1987; Doolittle, 1987; Truman et al., 1988; Doolittle and Asmussen, 1992), spodic horizons (Collins and Doolittle, 1987; Doolittle, 1987; Burgoa et al., 1991), placic horizons (Lapen et al., 1996), and buried palaeosols (Chapman et al., 2009). These diagnostic horizons generally have well-defined upper boundaries that have abrupt increases in bulk density, clay (argillic horizon), organic C complexed with Fe and Al (spodic horizon), or cemented Fe, Mn, or Fe-humus complexes (placic horizon). GPR has also been used to determine the thickness of albic horizons (E horizons) and evaluate the depth, lateral extent, and continuity of duripans, petrocalcic, and petroferric horizons (Doolittle et al., 2005), fragipans (Olson and Doolittle, 1985; Lyons et al., 1988; Doolittle et al., 2000), ortstein layers (Mokma et al., 1990a), and traffic pans (Raper et al., 1990). In these reports, the diagnostic horizons evaluated have distinct properties that enhanced their detection with GPR including cementation and induration (duripan, ortstein, petrocalcic, and petroferric horizons) and/or high bulk density (fragipans and traffic pans).

Ground-penetrating radar has been used to infer marked changes in soil color associated with abrupt and contrasting changes in organic carbon contents (Collins and Doolittle, 1987). GPR has also been used to infer the concentration of clay lamellae (Farrish et al., 1990; Mokma et al., 1990b; Tomer et al., 1996) and plinthite (Doolittle et al., 2005) in soils. Steelman and Endres (2009) used GPR to monitor soil freezing and the seasonal development of surficial, seasonally frozen soil layers. In areas of permafrost, GPR has been used to estimate the thickness of the active layer (Doolittle et al., 1990b) and to identify ice wedges (Hinkel et al., 2001).

In evaluations of a landscape in Pennsylvania containing Erie (fine-loamy, mixed, active, mesic Aeric Fragiaquepts) soils that have a fragipan and Fremont (fine-loamy, mixed, semiactive, acid, mesic Aeric Endoaquepts) soils that lack a fragipan, the radar record (collected with a 400 MHz antenna) has a seemingly continuous interface that grades from well to very poorly expressed (identified by a continuous line) at depths ranging from about 25 to 53 cm below the soil surface (Figure 39.7). Ground truth observations indicated that in areas where this interface had higher-amplitude reflections (lighter colors), the soil had a fragipan (Erie). In contrast, where the interface was denoted by lower amplitude reflections (black or darker colors) the soil had fragic properties but lacked a true fragipan and was considered to be Fremont. Multiple radar traverses across the landscape indicated that Fremont was the more abundant soil in the area.

Radar records of deep, sandy, excessively drained Valentine soils (mixed, mesic Typic Ustipsamments) in the Nebraska Sand Hills indicates thin, distinct, discontinuous, inclined to wavy bands throughout the soil (Figure 39.8b). These bands correspond to thin (<7.5 cm thick) layers of oriented clay on or bridging grains (lamellae) that are common in these sandy soils (Soil Survey Division Staff, 1999; Figure 39.8a). The radar record in Figure 39.8b has been surface normalized to correct the radar record for changes in elevation to produce graphic displays that
FIGURE 39.7   Radar record (b) showing a continuous subsurface interface with intermittent fragic properties in an area of Erie soils (a) in western Pennsylvania.

FIGURE 39.8   Surface normalized radar record (b) from an area of Valentine soils (a) in western Nebraska with discontinuous, inclined-to-wavy, thin bands of lamellae.

more closely resemble the topography of the landform and the soil horizons or features.

In areas of Valentine soils, the penetration depth of GPR typically ranges from about 2 to 5 m, which is less than expected for a very deep, excessively drained sandy soil. The presence of small amounts of clay in the lamellae, however, increases signal attenuation and reduces penetration depths (Harari, 1996; Olhoeft, 1998). In some soils, clay contents of only 5%–10% have been reported to reduce penetration depths to less than 1 m (Walther et al., 1986). Additionally, soils, such as Valentine, with an abundance of smectite or vermiculite, and associated relatively high CEC are more attenuating to GPR than soils with low-activity clay minerals.

In many upland areas, rock fragments and irregular or weathered bedrock surfaces limit the effectiveness of conventional methods to examine soil profiles and determine the depth to bedrock. In these areas, GPR is more reliable and effective than traditional soil surveying tools for determining the depth to bedrock and the composition of soil map units based on soil-depth criteria (Collins et al., 1989; Schellentrager and Doolittle, 1991). As seen in radar record shown in Figure 39.9b, the soil/bedrock interface can provide an abrupt, well-expressed, and easily identifiable reflector.

In some soils, however, coarse fragments in the overlying soil, irregular bedrock surfaces, fracturing, and the presence of saprolite make the identification of the soil/bedrock interface on radar records more ambiguous. Even with these limitations, GPR can be an effective tool for evaluating bedrock depths (Collins et al., 1989; Davis and Annan, 1989; Gerber et al., 2010) and changes in rock type (Davis and Annan, 1989), characterizing internal bedding, cleavage and fracture planes (Holloway and Mugford, 1990; Stevens et al., 1995; Toshioka et al., 1995;
FIGURE 39.9 Radar record (b) collected with a 400 MHz antenna showing soil/bedrock interface in area of Monson soils (a) in central Maine.

Lane et al., 2000; Grasmueck et al., 2004; Nascimento da Silva et al., 2004; Porsani et al., 2005), and identifying cavities, sinkholes, and fractures in limestone (Barr, 1993; Pipan et al., 2000; Al-fares et al., 2002).

One example of the use of GPR over bedrock is a radar record from an area of Monson soils (loamy, isotic, frigid Lithic Haplorthods) in central Maine (Figure 39.9). This shallow, somewhat excessively drained soil formed in a thin mantle of glacial till over slate, phyllite, or schist. The phyllite shown in the photograph contains a large number of narrow, closely spaced, vertical fractures, which cannot be effectively resolved with the 200 MHz antenna used to collect the 2D radar record. Because of scattering losses, attenuation, wavelength scale heterogeneities, and geometric constraints, the number of fractures interpreted from radar data is an order of magnitude less than the number observed in outcrops (Lane et al., 2000). In addition, fractures with large dip angles reflect very little radar energy back to the antenna and are not accurately imaged because of spatial aliasing distortion (Lane et al., 2000). Fractures filled with water or saturated materials produce higher-amplitude reflections than air-filled or unsaturated fractures (Lane et al., 2000).

Ground-penetrating radar also has been used to improve soil-landscape models and soil map unit design on glacial-scoured uplands (Doolittle et al., 1988), former periglacial environments (Doolittle and Nelson, 2009; Gerber et al., 2010), wetland catenas (Lapen et al., 1996), and coastal plain sediments (Rebertus et al., 1989; Puckett et al., 1990). The use of GPR to improve soil-landscape models, however, has been limited.

Ground-penetrating radar has been extensively used in the investigation of peatlands. Compared with traditional coring methods, GPR provides a more rapid and efficient means for estimating the thickness and characterizing the subsurface topography of organic deposits (Ulriksen, 1980, 1982). GPR has been used to estimate the thickness and volume of organic deposits (Ulriksen, 1982; Shih and Doolittle, 1984; Tolonen et al., 1984; Collins et al., 1986; Worsfold et al., 1986; Welsby, 1988; Doolittle et al., 1990a; Pelletier et al., 1991; Hanninen, 1992; Turenne et al., 2006), to distinguish layers having differences in degree of humification and volumetric water content (Ulriksen, 1982; Tolonen et al., 1984; Worsfold et al., 1986; Chernetsov et al., 1988; Theimer et al., 1994; Lapen et al., 1996), and to classify organic soils (Collins et al., 1986). Lowe (1985) used GPR to estimate the number of logs and stumps buried in peatlands. More recently, GPR has been used in peatlands to study subsurface piping (Holden et al., 2002), permafrost (Moorman et al., 2003), and subsurface deposits and hydrostratigraphy (Comas et al., 2004, 2005; Kettridge et al., 2008; Lowry et al., 2009). Peatlands often display considerable anisotropy in composition, moisture content, and bulk density (Warner et al., 1990), and such differences have allowed separation of organic layers that differ in degree of humification, bulk density, and dielectric permittivity (Tolonen et al., 1982; Chernetsov et al., 1988; Hanninen, 1992; Nobes and Warner, 1992; Theimer et al., 1994; Mellett, 1995; Comas et al., 2005; Lowry et al., 2009). The successful identification of interfaces resulting from differences in water content and degree of humification, however, has not been universal (Wastiaux et al., 2000; Sass et al., 2010).

Figure 39.10 is a radar record obtained with a 70 MHz antenna in a ponded area of Carlisle (euic, mesic Typic Haplosaprists) soils in northwestern Rhode Island. On this radar record, the upper 80–90 cm is plagued by parallel bands of background noise caused by reflected signals from the air/ice and ice/water interfaces. Changes in reflective patterns and signal amplitudes are evident at a depth of about 90 cm, which represents the water/organic matter interface. On this radar record, the organic/mineral soil interface is easily identified (a segmented
FIGURE 39.10 Radar record collected with a 70 MHz antenna over an inundated peatland in Rhode Island. A segmented line is used to highlight the organic/mineral soil interface. Arrows indicate locations of some buried logs, larger roots, or stumps. Scales are in meter.

line denotes the approximate location of this interface). This interface can be traced with reasonable confidence to a depth of about 675 cm (the maximum depth scanned). Buried logs and stumps produce hyperbolic reflections (indicted by arrows) within the organic materials.

Profiling depths of greater than 8 m have been reported in peatlands with low electrical conductivity (Ulriksen, 1980; Lowe, 1985; Worsfold et al., 1986; Theimer et al., 1994; Comas et al., 2005; Lowry et al., 2009), but GPR does not provide similar penetration depths in all organic soils. Penetration depths are largely affected by the specific conductance of the pore water (Theimer et al., 1994; Comas et al., 2005; Lowry et al., 2009). GPR is ineffective in coastal peatlands that are tidally influenced, contain sulfidic materials, and/or have high electrical conductivities. In noncoastal areas, GPR is generally more effective in acidic than alkaline peatlands. Lower frequency (<200 MHz) antennas are typically more effective for evaluating peatlands. In higher latitudes, peatlands are often surveyed during winter months, when surface layers are frozen and snow covered and can be easily traversed on foot or with snowmobiles or tracked vehicles. In lower latitudes, grass and reed covered peatlands have been successfully surveyed with airboats. Pelletier et al. (1991) described the use of helicopters to survey extensive peatlands in remote areas of Ontario.

39.3.3.2 GPR Evaluations of Groundwater, Soil Moisture, and Preferential Flow

Ground-penetrating radar has been used extensively for hydropedological investigations. In areas of coarse-textured soils, GPR has been used to chart water table depths among monitoring wells and into nearby areas (Sellmann et al., 1983; Davis et al., 1984; Wright et al., 1984; Shih et al., 1986; Johnson, 1987; Truman et al., 1988; Bohling et al., 1989; Smith et al., 1992; Iivari and Doolittle, 1994; Doolittle et al., 2006a). In addition, GPR has been used to design hydrologic models (Violette, 1987; Taylor and Baker, 1988), define recharge and discharge areas (Johnson, 1987; Bohling et al., 1989), predict groundwater flow patterns (Steenhuis et al., 1990; Iivari and Doolittle, 1994; van Overmeeren, 2004; Doolittle et al., 2006a), and delineate near-surface hydrologic conditions (Beres and Haeni, 1991; van Overmeeren, 1998). Collins et al. (1994) used GPR to identify and size subsurface cavities that influence preferential flow in a karst landscape; this information was used to improve contaminant transport models.

Radar records from an area of sandy Oakville (mixed, mesic Typic Udipsamments) soils formed in aeolian dunes in northwestern Indiana indicated depth to the water table ranging from 1.1 to 6.4 m (Figure 39.11; surface elevation has been normalized). Bedding planes within the dune and contrasting strata can

FIGURE 39.11 Surface-normalized radar record obtained with a 200 MHz antenna across a low aeolian dune in northwestern Indiana showing a water table as high-amplitude linear reflections, which stretch across the image.

be observed on the radar record. Reflections from the interior of dunes are largely produced by differences in moisture contents and differences in density and grain size between strata (Schenk et al., 1993; Harari, 1996).

At intermediate (field or catchment) scales, GPR has been used to map spatiotemporal variations in SWC (Lesmes et al., 1999; Huisman et al., 2001, 2002, 2003; Hubbard et al., 2002; Galagedara et al., 2003; Grote et al., 2003). A GPR method known as ground wave analysis has been used to measure the SWC of surface layers (Huisman et al., 2001). The ground wave is the portion of the energy that travels directly from a transmitting to a receiving antenna through the upper part of the soil. The velocity of the ground wave is strongly dependent on the water content of the upper few centimeters of the soil (Huisman et al., 2002). The volume of soil evaluated in ground wave analysis is determined by the antenna separation, width of the antenna, and depth of ground wave influence (Huisman et al., 2002). The depth of ground wave influence is typically 10–50 cm but is not well defined and decreases with increasing SWC (Huisman et al., 2002).

Ground-penetrating radar has been used to study preferential pathways in soils (Vellidis et al., 1990; Kung and Donohue, 1991; Kung and Lu, 1993; Boll et al., 1996; Tomer et al., 1996; Steenhuis et al., 1998). These studies have been conducted on sandy soils and under conditions favorable to GPR evaluations. However, Gish et al. (2002) used GPR data to locate and characterize soil layers that control subsurface flow at field scales in medium- and fine-textured soils. Using high-frequency antennas (450 or 500 MHz), these workers used GPR to identify depth to restrictive soil layers and the locations of discontinuities or breaks in these layers.

39.4 Electromagnetic Induction

39.4.1 Overview of Electromagnetic Induction

39.4.1.1 Principles of Operation

Electromagnetic induction methods involve the use of instruments known as ground conductivity meters (GCM), which consist of a transmitter coil and either one or two receiver coil(s) spaced at a set distance(s) apart. Ground conductivity meters operate by generating an alternating electrical current, which is passed through the transmitter coil. This alternating electrical current generates a time-varying electromagnetic field above the surface; the primary electromagnetic field. The primary electromagnetic field induces eddy currents that flow through the soil and generate a secondary electromagnetic field, which propagates through the ground. The secondary field is proportional to the ground current and is used to calculate the soil's "apparent" or "bulk" electrical conductivity. The amplitude and phase of these two electromagnetic fields are measured by the receiver coil(s).

Apparent conductivity (EC_a) is a weighted, average measurement for a column of earthen materials to a specific depth (Greenhouse and Slaine, 1983) and is a measure of the soil's ability to conduct electrical current. Variations in EC_a result from changes in the electrical conductivity of earthen materials, which is influenced by the type and concentration of ions in solution, the amount and type of clay in the soil matrix, the volumetric water content, and the temperature and phase of the soil water (McNeill, 1980). The EC_a of soils will increase with increases in soluble salts, water content, and/or clay contents (Rhoades et al., 1976; Kachanoski et al., 1988).

Even though interpretations are complicated by the interaction of multiple soil properties, EC_a has been used to infer and map variations in soils and soil properties at different spatial scales and levels of resolution. Variations in EC_a have been associated with changes in particle-size distribution, clay mineralogy, bulk density, CEC, salinity, plant nutrients, organic C concentration, and water content. Presently, EC_a mapping is recognized as one of the most valuable methods in agriculture for measuring the spatial variability of soils and soil properties at field and landscape scales (Corwin, 2008; Lück et al., 2009).

Electromagnetic induction is not suitable for use in all soil investigations. Generally, EMI has been most successful in areas where subsurface properties are reasonably homogeneous, the effects of one property (e.g., clay, water, or salt content) dominates over other properties, and variations in EC_a can be directly associated with changes in the dominant property affecting EC_a (Cook and Walker, et al., 1992). A weakness of this interpretative process is "equivalence" when several interacting properties can produce similar EMI responses. As an example, the simultaneous interaction of soil depth, clay, and moisture contents can lower the relationship of EC_a with any one of these properties alone. An increase in clay content will produce higher EC_a. Spatially, however, the increase in EC_a associated with an increase in clay can be offset by reduced soil depth over more electrically resistive materials and/or lower water content, both of which lower the measured EC_a. These three interacting and spatially varying soil properties can result in EC_a measurements that are difficult to associate with one soil property (e.g., clay content) alone. Because of equivalence, tacit knowledge, onsite soil sampling, and data analysis are required to decipher the exact site-specific causes for the variability in EC_a (Sommer et al., 2003).

Relationships between EC_a and soil properties can vary over short distances and foster inconsistent or ambiguous results (Carroll and Oliver, 2005). The effectiveness of EMI as a soil-mapping tool will depend upon the degree to which differences in physiochemical soil properties that affect EC_a correspond to differences in soil types. If a strong and meaningful relationship is established between soils and EC_a, field-scale EC_a mapping can be used to identify distinct zones, each with relatively homogenous soils and soil properties (Johnson et al., 2001).

39.4.1.2 Depth of Penetration

The depth of penetration of the electromagnetic current in the soil is dependent on the geometry (spacing and orientation) of the coils, frequency of the induced current, height above the soil surface, and the conductivity of the profiled material(s). The orientation of the transmitter and receiver coil axis (with respect to

the ground surface) affects the response from materials at different depths (McNeill, 1980). In the horizontal dipole orientation (HDO) or perpendicular geometry (PRP), GCMs are more sensitive to surface materials. In the vertical dipole orientation (VDO) or horizontal coplanar geometry (HCP), GCMs are more sensitive to deeper materials.

In most studies, a single GCM is used. The choice of GCM will depend on the objectives of the survey, soil conditions, and the desired depth of penetration (Lück et al., 2009). In the United States, the most widely used GCM in agriculture is the EM38 meter (Geonics Limited, Mississauga, Ontario) and the Dualem-1S meter (Dualem, Inc., Milton, Ontario), which have maximum theoretical penetration depths of 1.5 m. For these GCMs, the depth of penetration is considered "geometry limited" rather than "skin depth limited" because penetration depth is a function of the distance between the transmitter and receiver coils (McNeill, 1996). For geometry limited GCMs, larger intercoil spacings and lower operating frequency result in greater penetration depths. For multifrequency GCMs developed by Geophex Limited (Raleigh, NC) and GSSI (Salem, NH), the depth of penetration is dependent upon the operating frequency and the EC_a of the profiled material(s). With these GCMs, the depth of penetration is considered "skin depth limited" rather than "geometry limited" (Won, 1980, 1983; Won et al., 1996). Skin depth represents the maximum depth of penetration for a GCM operating at a specified frequency and sounding a medium of known conductivity. The skin depth (D) can be estimated using the following equation (McNeill, 1996):

$$D = \frac{500}{(sf)^{-2}}, \qquad (39.6)$$

where
    s is the ground conductivity (mS m^{-1})
    f is the frequency (kHz)

According to Equation 39.6, skin depth is inversely related to the operating frequency and the conductivity of the earthen materials. Low-frequency signals have longer periods of oscillation, lose energy less rapidly and, therefore, travel farther than high-frequency signals. Multifrequency sounding allows multiple depths to be profiled with one pass of the sensor (Won et al., 1996).

For all GCMs, surface and shallow layers contribute more to the overall response than deeper layers. de Jong et al. (1979) and Slavich (1990) reported that the actual depth of penetration is not fixed, but will vary depending on the EC_a of the profiled material(s). In general, GCMs will see deeper in electrically resistive than in conductive soils (Won et al., 1996).

Each instrument has characteristic depth sensitivity response curves. The theoretical depth of penetration has been arbitrarily defined as the depth at which 70% of a GCM's cumulative response is obtained in the overlying soil volume (Saey et al., 2008). Although contributions to the measured response come

from all depths within the theoretical depth of penetration, the largest contribution to the response comes from the "depth of observation," which is the depth that has the greatest contribution to the measured EC_a (Roy and Apparao, 1971). As noted by Roy and Apparao (1971), for all GCM, the depth of observation is often considerably shallower than the theoretical penetration depth specified by manufacturers. In saline soils, the high conductivity of surface and near-surface soil horizons contributes greatly to the depth-weighted response of GCMs and limits the depth of observation. In areas of highly conductive soils, manufacturer's specifications or skin depth estimations may provide fairly accurate estimates of the theoretical depth of penetration, but greatly overestimate the depth of observation.

The response of GCMs (EC_a) is directly proportional to the electrical conductivity of the soil under conditions of low induction numbers. These conditions (low induction numbers) are met when the intercoil spacing is less than the skin depth. Conditions of low induction numbers are typically satisfied in soils having relatively low conductivities (<100 mS m^{-1}) (McNeill, 1980). In saline soils, however, the low induction numbers condition is not fulfilled, and EC_a is not directly proportional to the electrical conductivity of the soil.

39.4.1.3 Temperature Effects

Soil electrical conductivity is an electrolytic process that is a function of the concentration and mobility of the dissolved ions present in the soil solution and on the surfaces of soil particles, and thus, is dependent on the temperature and phase of the soil water (Allred et al., 2005). Air temperature does not directly affect soil electrical conductivity, but does contribute to the instrument "drift" reported in some studies (Allred et al., 2005). Variations in soil temperature, however, do affect EC_a. As soil temperatures increase, the viscosity of water decreases, the mobility of dissolved ion increases, and, as a consequence, EC_a increases (McNeill, 1980; Allred et al., 2005). Seasonal fluctuations in soil temperature are greatest in the upper part of soil profiles and have the greatest affects on EC_a. Brevik et al. (2004) observed that daily changes in soil temperatures within the upper 10 cm do not significantly influence EC_a. Results from studies conducted by Allred et al. (2005) suggest a soil temperature threshold of 8°C, below which there is a substantial reduction in measured EC_a, especially when the soil is frozen. Apparent conductivity measurements are unreliable when frozen layers are present in soils (McKenzie et al., 1989).

Electrical conductivity increases at a rate of approximately 1.9% per °C increase. McKenzie et al. (1989), working on saline soils, stressed the importance of correcting the soil temperature to a standard temperature for more accurate conversions of EC_a to saturated paste electrical conductivity (EC_e). When comparing results from EMI surveys of the same area that are completed at different times of the year, the effect of temperature on EC_a is important and customarily expressed at a reference temperature of 25°C. The EC_a can be adjusted to a reference EC at 25°C (EC_{25})

using the following equation (United States Salinity Laboratory Staff, 1954):

$$EC_{25} = f_t EC_t, \quad (39.7)$$

where

f_t is a temperature conversion factor (see Table 15 in United States Salinity Laboratory Staff, 1954)

EC_t is the EC_a measured at a particular temperature

Approximations for the temperature conversion factor are also available in polynomial form (Stogryn, 1971; Rhoades et al., 1999; Wraith and Or, 1999) or other temperature conversion equations such as the one modified from Sheets and Hendrickx (1995) by Corwin and Lesch (2005):

$$EC_{25} = 0.4470 = 1.4034 \exp\left(-\frac{T}{26.8150}\right). \quad (39.8)$$

In most studies, only a single soil temperature is measured. A common concern is the depth at which the measurement should be made. Lück et al. (2009) suggested that because the maximum sensitivity of the EM38 meter operated in the vertical dipole orientation is between depths of 30–50 cm, temperature measurements should be made within this depth interval.

Changes in air temperature, humidity, and atmospheric electricity (spherics) affect the stability or drift of GCMs (Sudduth et al., 2003). Sudduth et al. (2001) reported instrument drifts as great as 3 mS m^{-1} for the EM38 meter. The causes for this drift are not entirely due to variations in air temperature but are a function of instrument instability over time (Sudduth et al., 2001). Instrument drift is more noticeable and has a greater impact on interpretations in areas of low EC_a. Suggested methods to minimize instrument drift include the use of a calibration traverse line (Sudduth et al., 2001), ample instrument warm-up time, shading the meter, and conducting surveys when temperatures are below 40°C (Robinson et al., 2004).

39.4.1.4 Instruments

An increasing number of commercially available GCMs are available (see Figure 39.12). Ground conductivity meters commonly used in soil investigations include the Dualem-1S and Dualem-2 meters (Dualem, Inc.); the EM31, EM38, EM38DD, and EM38-MK2 meters (Geonics Limited); GEM-2 sensor (Geophex Limited); and Profiler EMP-400 (Geophysical Survey

FIGURE 39.12 Selected EMI equipment. Pictured are the Veris Soil EC 3100 mapping system (a); the Profiler EMP-400 multifrequency sensor (b); the EM38 meter (c); and the Dualem-2 meter (d).

Systems, Inc.). The dual-geometry configuration of Dualem meters, the dual dipole orientations of the EM38DD meter, and the dual receiver–transmitter spacings of the EM38-MK2 meter allow simultaneous measurement of EC_a over two separate depth intervals. The aforementioned GCMs all have standard connectors for GPS communication and support data loggers and proprietary software, which are used to record and integrate EC_a and GPS data. Some GCMs, such as the multifrequency Profiler EMP-400, come with internal GPS.

Another sensor that is commonly used in precision agriculture and soil investigations is the towed-array resistivity [ER] unit (Figure 39.12a). This ER sensor measures the potential gradient resulting from the injection of electrical current into the soil through coulter electrodes. Soundings and profiles are made with an arrangement of current and potential electrodes known as arrays. The depth of penetration is "geometry limited" and dependent upon the spacing and the arrangement of the electrodes. Arrays are connected to a field computer or data logger and integrated with GPS. Compared with GCMs, towed-array resistivity units do not experience instrument drift, and are less susceptible to spherics and engine noise interference. However, towed-array resistivity units are invasive and require good ground contact. As a consequence, the use of towed-array resistivity units is restricted in cultivated fields and over rocky or frozen grounds.

In the United States, several towed-array resistivity units are manufactured by Veris Technologies (Salina, KS). Towed-array resistivity units used in agriculture include the Veris Soil EC 2000, 3100, and 3500 mapping systems. These mapping systems utilize direct-contact, coulter electrodes that are arranged in a modified Wenner configuration (Lund et al., 2000).

Each of the aforementioned GCM and ER instruments has distinct operational advantages and disadvantages (Sudduth et al., 2003). Comparative studies have generally revealed close similarities between EC_a data collected with different instruments (Sudduth et al., 1999, 2003; Doolittle et al., 2001, 2002a; Saey et al., 2008). However, differences in sensor calibration, depth sensitivity curves, and volume of soil material measured will affect measurements and result in slightly different EC_a values. In comparative studies using different GCM and ER units, the highest correlations were obtained with sensors having similar depth sensitivity curves (Sudduth et al., 1999, 2003). In general, differences in EC_a maps produced from data collected with different GCMs or ER units have been more noticeable over soils with highly contrasting layers (Sudduth et al., 2003).

39.4.2 Field Methodology

The speed, economy, and simplicity of EMI make this geophysical method attractive in agriculture. In the past, grids were laid out across survey areas and EC_a measurements were obtained at discrete stations, typically represented by the grid intersections. Presently, the synergism of EMI, GPS, and field data recording systems has enabled the rapid collection, storage, and processing of larger data sets and the more comprehensive coverage of sites. The speed and ease at which data are georeferenced and recorded greatly reduces survey time and makes practical the surveying of large areas. Kitchen et al. (2003, 2005) discuss the integration of EMI and GPS technologies to improve interpretations.

Integrated systems have been used at various spatial scales to map soil EC_a using either point or continuous sampling methods. Point sampling methods measure EC_a at specific stations, which are often located within a predetermined grid or at random points within a survey area. With this method, establishment of a grid and the positioning of measurement points are more time-consuming than the actual collection of EC_a data. As a consequence, compared with continuous sampling methods, the number of observation is often less for surveys conducted using point sampling methods. However, because of the greater time spent at each measurement point, a greater number of EC_a and position measurements can be collected and averaged. This procedure is known as "stacking" and is used to reduce unwanted background noise and improve data quality, but its use increases the time needed to complete the EMI survey. With the point sampling method, the operator typically moves sequentially along grid or traverse lines and measures EC_a in two dipole orientations or geometries. This method has been used most often for EMI surveys of small research areas (typically less than 40 ha) (Hendrickx et al., 1992; Khakural et al., 1998; Lesch et al., 1998; James et al., 2003; Jung et al., 2005).

Electromagnetic induction surveys of very large areas (300–10,000 km^2) have required larger grid intervals with more widely spaced stations. For surveys of very large areas, the spacing between measurement points has ranged from 0.5 (Williams and Arunin, 1990) to 5 km (Williams and Baker, 1982). Apparent conductivity data will be more generalized in surveys of very large areas as the short-range variability in soils and soil properties is masked by the coarse grid scale.

Continuous, simultaneous recording of both GPS and EC_a data in field computers as the GCM or ER is moved along traverse lines (continuous sampling) produces a greater number of measurements, provides more complete coverage of sites, and is less time-consuming than point sampling methods. Continuous sampling methods, however, may result in reduced positional accuracy, and GCMs must remain stable and in a fixed orientation when operated in the continuous mode. Consequently, either two separate surveys are required to collect EC_a data in both dipole orientations, or a GCM with a dual-geometry configuration, dual receiver–transmitter spacings, or multiple frequencies must be used to simultaneously collect measurements over different depth intervals.

Depending on the size of the survey area and the resources available, either a mobile or pedestrian survey is used to collect EC_a data. For large, open areas or whenever the total number of observations exceeds 1600 data points, Freeland et al. (2002) recommended the use of mobile over pedestrian surveys. In large open fields, mobile surveys provide more comprehensive

coverage, greater acquisition efficiency, and less operator fatigue than pedestrian surveys (Cannon et al., 1994; Chen et al., 2000; Johnson et al., 2001; Corwin et al., 2003; Greve and Greve, 2004; Corwin et al., 2006). Cannon et al. (1994) reported a fivefold increase in productivity when mobile survey methods were used instead of pedestrian survey methods. However, in rough terrain and under unfavorable field conditions, mobile EMI surveys are impractical and pedestrian surveys must be carried out.

For continuous sampling methods, the inline (along traverse lines) and lateral (distance between traverse lines) sampling intensities are more critical to map quality (precision and accuracy of boundaries) than the applied interpolation technique (e.g., kriging, inverse distance) (James et al., 2003; Farahani and Flynn, 2007). In general, slower speeds of advance, smaller traverse line spacing, and faster data acquisition rates lead to higher sampling intensities and map quality (Farahani and Flynn, 2007). These workers found that map quality decreased only slightly as the interval between traverse lines was increased from 2.5 to 50 m. As the interval between traverse lines was increased to greater than 80 m, however, map quality declined very rapidly as map delineations became highly distorted and incorrectly classified. King et al. (2001) considered a traverse line spacing of about 24 m reasonable for larger fields. Using these examples as guidelines, the final decision on the most suitable traverse spacing should be tempered by tacit knowledge of the soils and expert site assessments.

39.4.3 Applications

Apparent conductivity maps have been used to identify soil and management zones and to predict differences in soils, soil properties, and crop yields. Differences in EC_a have been associated with spatial changes in one or more specific soil physiochemical properties. Electromagnetic induction has been used to assess and map soil salinity, assist site-specific management, characterize variability in soil physiochemical properties, and direct soil sampling.

39.4.3.1 Soil Salinity Assessment

Methods commonly used to appraise soil salinity include: (1) visual observation of crop appearance (Soil Survey Division Staff, 1993), (2) sampling and measurement of the saturated paste extract (EC_e) (United States Salinity Laboratory Staff, 1954), (3) Wenner array or four-electrode sensor (Halverson et al., 1977; Nadler, 1981), (4) EMI (Corwin and Rhoades, 1982, 1984, 1990; Williams and Baker, 1982; Wollenhaupt et al., 1986; McKenzie et al., 1989; Rhoades et al., 1989a, 1989b), and (5) multi- and hyperspectral imagery (Corwin, 2008).

In soil surveys, visual crop observations and saturated paste extract method are the most commonly used methods to distinguish and map phases of soil salinity (United States Salinity Laboratory Staff, 1954; Soil Survey Division Staff, 1993). While visual observations are adequate for salinity mapping, these interpretations provide only a qualitative measure of soil salinity and are dependent on the presence of plant cover and surface salts. The saturated paste extract method is commonly accepted as the most accurate measure of soil salinity (McNeill, 1985), but it requires considerable resources for field sampling and laboratory analysis. Thus, only a limited number of soil samples can be collected and analyzed. Because of the limited sample numbers and the high spatial variability of soil salinity, analysis of saturated paste extracts is of limited value for the assessment of soil salinity across large management units or for soil surveys (Corwin, 2008).

In the early 1970s, the USDA-ARS Salinity Laboratory began to use bulk soil electrical conductivity as a field measure of soil salinity (Rhoades and Ingvalson, 1971), and techniques to evaluate salinity with EMI were subsequently developed (de Jong et al., 1979; Rhoades and Corwin, 1981;Williams and Baker, 1982). This early research was directed principally toward the vertical profiling of salinity through the root zone (Corwin, 2008). Several empirical relationships were developed but were site specific and could not be extrapolated and used at other sites without calibration (Corwin, 2008).

A major challenge in using EMI to map soil salinity has been the conversion of apparent conductivity (EC_a) into the conductivity of the saturated paste extract (EC_e); the most commonly used measure of soil salinity. A number of models have been developed that relate EC_a to EC_e (Wollenhaupt et al., 1986; McKenzie et al., 1989; Rhoades et al., 1989a, 1989b; Corwin and Rhoades, 1990; Slavich, 1990; Cook and Walker, 1992; Lesch et al., 1995a, 1995b; Johnston et al., 1997). Depth-weighted calibration models (Wollenhaupt et al., 1986; McKenzie et al., 1989) are useful in mapping relative spatial differences in soil salinity within units of management, but do not assess salinity variation with depth in the profile (Cassel et al., 2009). Rhoades et al. (1989a, 1989b) developed empirical equations and coefficients for determining soil salinity at different depths across units of management using a dual pathway parallel conductance model. This deterministic model relies on estimates of water content, texture, bulk density, and soil temperature to estimate soil salinity from EC_a data. Multilinear regression models for determining soil salinity at different soil depth intervals from EC_a data were later developed (Lesch et al., 1992, 1995a, 1995b). These stochastic models are independent of the salinity profile shape, but require the collection and analysis of soil samples for calibration (Cassel et al., 2009). Unfortunately, models relating EC_a to EC_e are both time dependent and site specific (Lesch et al., 1998). As a consequence, calibration equations and modeled results usually cannot be extrapolated to other sites (Cassel et al., 2009). To potentially reduce the number of samples needed for model calibration, directed soil sampling models have developed to characterize spatial variations in soil salinity across units of management (Lesch et al., 1992).

In areas of saline soils, of the properties that influence EC_a, the concentration of soluble salts typically have the greatest effect on EC_a (van der Lelij, 1983; Johnston et al., 1997). Williams and Baker (1982) estimated that 65%–70% of the variation in EC_a in saline soils can be explained by changes in the concentration of soluble salts alone, and EC_a can provide reasonably accurate estimates of soil salinity (Williams and Baker, 1982; van der Lelij, 1983; Diaz and Herrero, 1992). Although the estimates of salinity levels are reasonably accurate, they may not meet accuracy standards for specific objectives (Rhoades et al., 1989a; Johnston et al., 1997).

39.4.3.2 Soil Property Prediction, Site-Specific Management, and High-Intensity Soil Surveys

Apparent conductivity is a helpful surrogate for characterizing the variability of soil properties that are too difficult, time-consuming, or expensive to measure by other means (Jaynes, 1995; Stafford, 2000; Corwin et al., 2008). As apparent conductivity is a function of several interacting soil properties, the use of EC_a to characterize the variability of a soil physiochemical property is not always straightforward and uncomplicated. Effective use of EMI to predict soil properties requires sampling and analysis of a limited number of ground-truth observations for site-specific calibration of EC_a to the property of interest.

In nonsaline soils, EC_a is largely affected by water content, clay content, mineralogy, CEC, and organic matter content, with reported correlations ranging from 0.4 to 0.8 (Farahani et al., 2005). Electromagnetic induction has been used extensively to assess depths to argillic horizons, claypans, fragipans (Stroh et al., 1993; Sudduth and Kitchen, 1993; Doolittle et al., 1994; Sudduth et al., 1995; Mueller et al., 2003), and bedrock (Zalasiewicz et al., 1985; Palacky and Stephens, 1990; Bork et al., 1998). Apparent conductivity has been used as a surrogate measure of SWC (Kachanoski et al., 1988, 1990; Sheets and Hendrickx, 1995; Khakural et al., 1998; Waine et al., 2000; Mueller et al., 2003; Hezarjaribi and Sourell, 2007; Huth and Poulton, 2007; Tromp-van Meerveld and McDonnell, 2009), clay content (Williams and Hoey, 1987; Mueller et al., 2003; Sommer et al., 2003; King et al., 2005; Weller et al., 2007; Cockx et al., 2009; Harvey and Morgan, 2009), CEC (Triantafilis et al., 2009), exchangeable Ca and Mg (McBride et al., 1990), soil pH (Bianchini and Mallarino, 2002), soil organic carbon (Jaynes, 1996; Johnson et al., 2001), field-scale leaching rates of solutes (Slavich and Yang, 1990), herbicide partition coefficients (Jaynes et al., 1994), and available N (Eigenberg et al., 2002). In these reported studies, EC_a was either directly related to the soil property under investigation or the property (such as soil organic carbon) was associated with a property (moisture and clay content) that the sensor measures. The strength and significance of the relationships among EC_a and other properties, however, can vary both within and among individual

fields (Bekele et al., 2005; Carroll and Oliver, 2005), and often EC_a has a complex relationship with different, interacting soil properties (Farahani et al., 2005).

Site-specific management adjusts farming practices to measured variations in soil properties by dividing farmlands into management zones that have different seeding and chemical requirements (Mulla, 1993). Electromagnetic induction and ER have been used as accurate, fast, and inexpensive means of mapping soils and soil properties at a level of resolution that meets the requirements of site-specific management (Jaynes et al., 1995; Sudduth et al., 1995; Lund et al., 2000; Bianchini and Mallarino, 2002; Corwin and Lesch, 2003; Godwin and Miller, 2003; Adamchuk et al., 2004; Hedley et al., 2004; Corwin et al., 2008). As large, high-resolution data sets can be collected from mobile EMI platforms equipped with GPS, EMI is well suited to surveying of large units of management (Freeland et al., 2002; Adamchuk et al., 2004).

Spatial EC_a data identifies areas with reasonably homogenous soils (Doolittle et al., 1996; Frogbrook and Oliver, 2007) and often corresponds well with soil patterns across the landscape. These data can provide information on the distribution of soils at different scales of resolution; from field and landscape scales (Khakural et al., 1998; King et al., 2005; Weller et al., 2007) to regional inventories (Brevik and Fenton, 2003; Harvey and Morgan, 2009). Soil surveys incorporating EC_a data may have greater detail than those prepared with conventional methods due to the spatial intensity and abundance of data (Jaynes, 1995; Hedley et al., 2004; Doolittle et al., 2008) and may more accurately identify small included areas of dissimilar soils (Fenton and Lauterbach, 1999).

Kravchenko (2008) and Kravchenko et al. (2002) used EC_a to distinguish soils belonging to different soil drainage classes. Several studies have associated changes in EC_a with changes in the clay content of soils (King et al., 2005; Weller et al., 2007; Harvey and Morgan, 2009). In Coastal Plain landscapes, Anderson-Cook et al. (2002) used EC_a to classify soil series with an accuracy of greater than 85%. Doolittle et al. (2008) used EC_a to identify and delineate soils to improve the quality of a high-intensity soil survey in Illinois, but independent observations showed only slight improvements in the taxonomic purity of the map units when EC_a data were used. Inclusion of EC_a data in the survey effort, however, resulted in refinement of map units and increased confidence in mapping decisions.

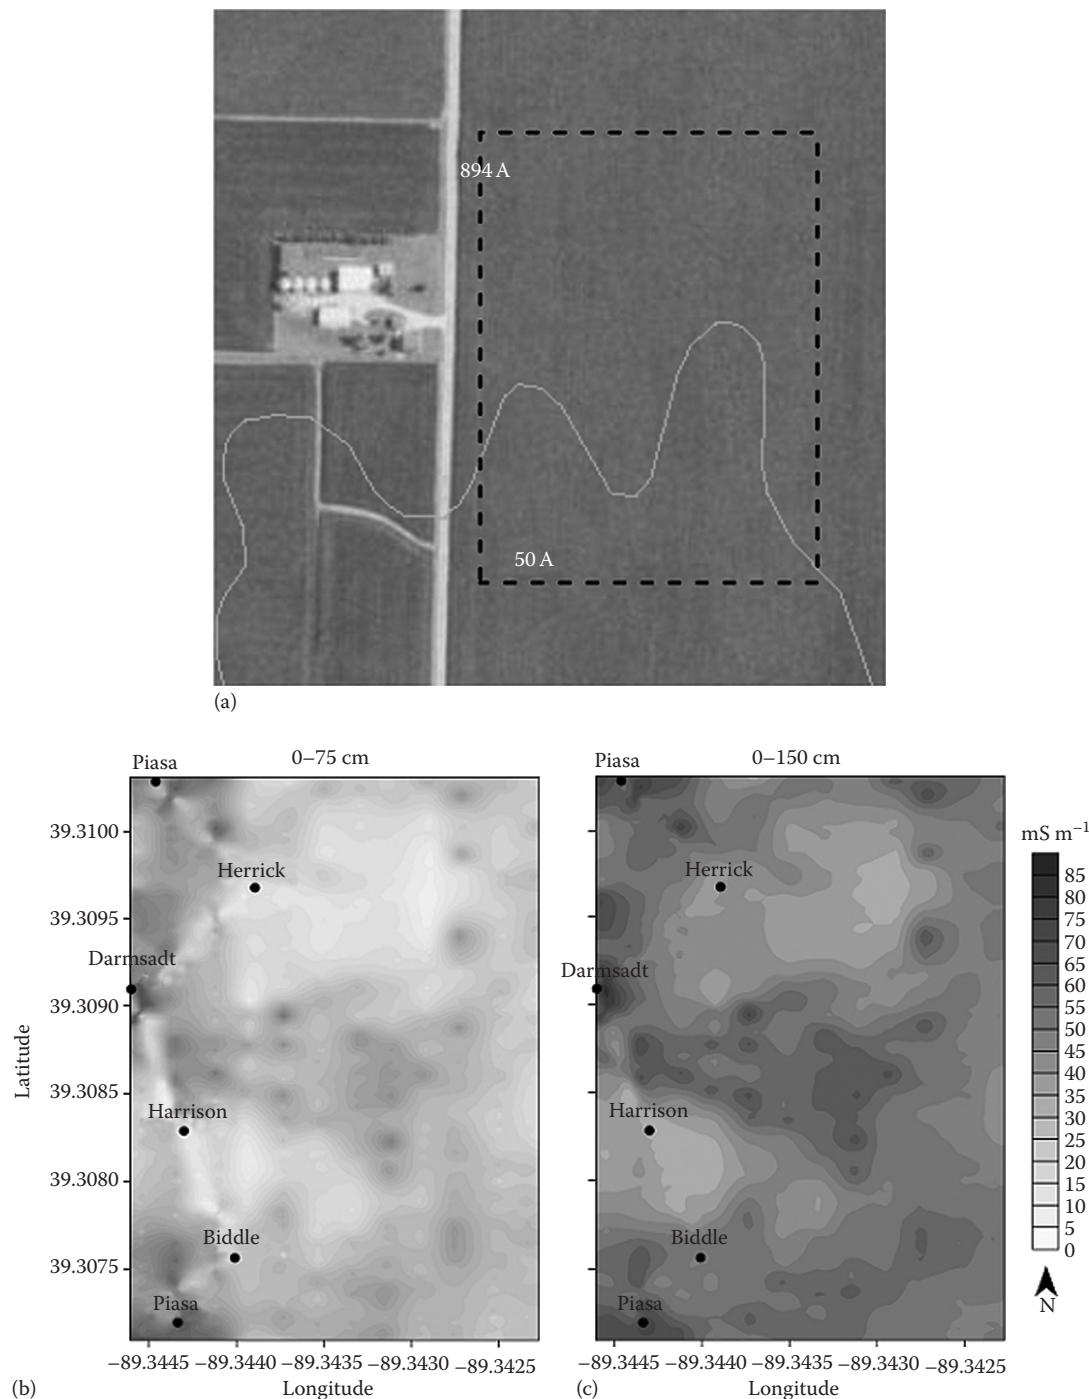
Maps of EC_a are frequently compared with soil maps to better understand and interpret the distribution and extent of soils within delineations, adjust the placement of soil boundary lines, and refine soil maps. An example of this qualitative methodology is an EMI survey that was conducted in south-central Illinois to determine the distribution of sodium-affected soils; Natrudalfs and Natraqualfs. In this landscape, Natrudalfs and Natraqualfs are intermingled with non-sodium-affected Argiudolls, Argiaquolls, and Endoaqualfs. Areas of the sodium-affected soils are variable in size, distribution, and shape;


FIGURE 39.13 EMI survey of a site in south-central Illinois. The location is outlined on the soil map (Soil Survey Staff, 2009) as shown in (a). Spatial distributions of EC_a collected with the EM38-MK2-2 meter operated in the VDO are shown in the two plots: one for the shallower sensing 50 cm (b) and one for the deeper sensing 100 cm (c) intercoil spacings.

and their extent in individual soil polygons is unknown. The study site (enclosed by rectangle on the soil map in Figure 39.13a) contains two relatively large delineations of Herrick–Biddle–Piasa silt loams, 0%–2% slopes (894A), and Virden silty clay loam, 0%–2% slopes (50A). Of the named soils, only Piasa is a sodium-affected soil (Table 39.1).

The EMI survey of the area (Figure 39.13b) indicated that EC_a ranged from 0.6 to 84.0 mS m^{-1} and increased with depth and proximity to the water table. From this survey, sites for soil description were located from visual examination of prominent EC_a zones, and the soil identified at each observation point (Figure 39.13b). The soils identified at the three observation sites in areas

TABLE 39.1 Taxonomic Classifications of the Soil Series Identified at the Central Illinois Site

Soil Series	Taxonomic Classification
Biddle	Fine, smectic, mesic Aquic Argiudolls
Darmstadt	Fine-silty, mixed, superactive, mesic Aquic Natrudalfs
Harrison	Fine-silty, mixed, superactive, mesic Oxyaquic Argiudolls
Herrick	Fine, smectitic, mesic Aquic Argiudolls
Oconee	Fine, smectitic, mesic Udollic Endoaqualfs
Piasa	Fine, smectitic, mesic Mollic Natraqualfs
Virden	Fine, smectitic, mesic Vertic Argiaquolls

of $EC_a > 60\,mS\,m^{-1}$ (in VDO) were identified as sodium-affected soils (Darmstadt and Piasa). In contrast, the sites in areas with $EC_a < 55\,mS\,m^{-1}$ (in VDO) were identified as the non-sodium-affected soils (Harrison, Biddle, and Herrick) (Table 39.1).

39.4.3.3 Directed Sampling

Software has been developed by the USDA-ARS Salinity Laboratory (Riverside, California) to select optimal soil sampling locations at field scales based on EC_a data (Lesch et al., 1995a, 1995b, 2000; Lesch, 2005). The ESAP (EC_e Sampling, Assessment, and Prediction) software though designed to predict EC_e from EC_a data can be used to predict other physiochemical properties as well. The program employs prediction-based sampling and modeling as a cost-effective alternative to geostatistical techniques, which are more sample intensive (Eigenberg et al., 2008). The ESAP methodology relies on high-density EC_a data to direct low-density soil sampling to calibrate suitable predictive equations. One of ESAP's components is the response surface sampling design (RSSD), which employs a directed-sampling approach to locate calibration sample points from observed locations and magnitudes of EC_a data (Lesch, 2005; Corwin et al., 2006; Eigenberg et al., 2008).

The ESAP-RSSD was used in a salinity assessment of a 16 ha field in Grand Forks County, North Dakota (Figure 39.14) to identify 20 optimally located sample points to characterize variability and to predict soil salinity across this unit of management. Because EC_a of measurements in the EM38DD HDO mode (shallow mode, ~0–75 cm) were less than those in the VDO mode (deep mode, ~0–150 cm), soils in this area were persumed to have a normal salt profile, that is, salt concentration increases with depth. The locations of the 20 RSSD-selected sampling sites and their numerical identifier are shown in Figure 39.14a.

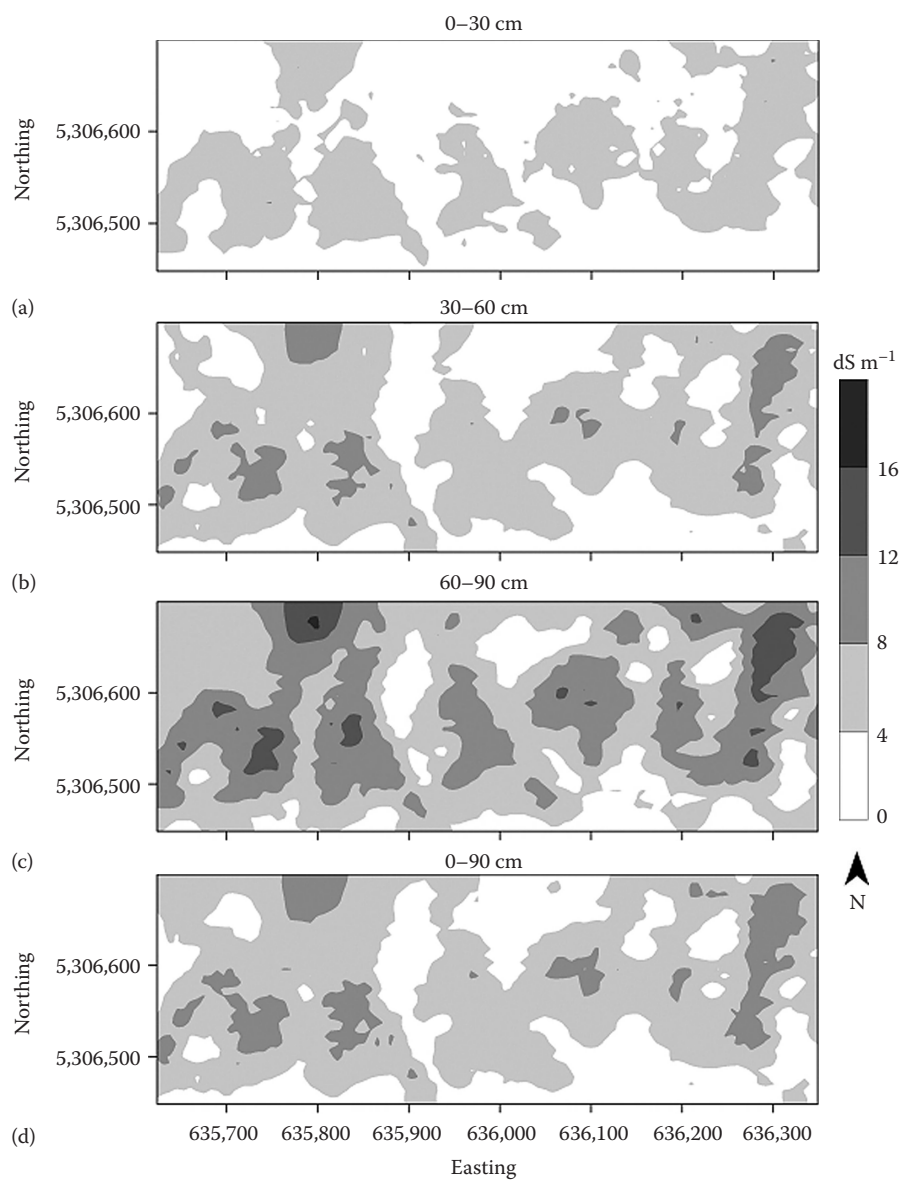
After laboratory data were available for soil layers sampled at each of the 20 sample points, the ESAP calibrate program was used to convert EC_a data into EC_e data using a stochastic calibration model (Lesch et al., 1992, 1995a, 1995b, 2000). This stochastic method uses multilinear regression models to predict EC_e from EC_a data and provide a spatial representation of soil EC_e across the area (Figure 39.15).
FIGURE 39.14 EC_a data from an area of saline Bearden soils in North Dakota. Data were collected with an EM38DD meter operated in the shallower sensing HDO (a) and the deeper sensing VDO (b). Numbers on the upper plot identify the locations of 20 sampling sites determined by the RSSD program of the ESAP software suite.


FIGURE 39.15   Distribution of estimated EC_e for different depth intervals ((a) 0–30 cm, (b) 30–60 cm, (c) 60–90 cm, and (d) 0–90 cm) within the Bearden saline site (Figure 39.14). Estimates from the stochastic model in the ESAP calibrate program.

Within the area evaluated, mean predicted EC_e ranged from 1.6 to 8.78 dS m^{-1} in the 0–30 and the 60–90 cm depth intervals, respectively (Table 39.2).

TABLE 39.2   Basic statistics for a field of saline Bearden soils in Grand Forks County, North Dakota. Data predicted for different soil depth intervals using the ESAP stochastic model. All EC_e values are expressed in dS m^{-1}

	0–30 cm	30–60 cm	60–90 cm	0–90 cm
Number	7040	7040	7040	7040
Minimum	0.00	0.00	1.08	0.38
25th percentile	2.39	3.28	4.60	1.36
75th percentile	4.76	6.47	9.28	6.83
Maximum	9.34	11.67	16.73	12.58
Mean	1.60	2.13	8.78	2.20

Mn: Pyrolusite, MnO_2
 Manganite, $\gamma\text{-MnOOH}$
Ti: Rutile, TiO_2

Mn: Romanechite, $Ba_{0.66}(Mn^{IV}Mn^{III})_5O_{10} \cdot 1.3H_2O$

Fe: Goethite, $\alpha\text{-FeOOH}$
Mn: Ramsdellite, MnO_2
 Groutite, $MnOOH$
Al: Diaspore, $\alpha\text{-AlOOH}$

Mn: Todorokite,
 $(Na,Ca,K)_{0.3-0.5}(Mn^{IV}Mn^{III})_6O_{12} \cdot 3.5H_2O$

Fe: Lepidocrocite, $\gamma\text{-FeOOH}$
Al: Boehmite, $\gamma\text{-AlOOH}$

Fe: Feroxyhyte, $\delta'\text{-FeOOH}$ (A = B = Fe)
Mn: Buserite (A = B = Mn)
 Lithiophorite, $(Li,Al)(Mn^{III},Mn^{IV})O_2(OH)_2$
 (A = Mn,Co; B = Al,Li,Ni,Cu,Zn)
 Asbolane, $(Co,Li)MnO_2(OH)_2$
 (A = Mn; B = Co,Ni)
Al: Gibbsite, bayerite, nordstrandite, $Al(OH)_3$
 (A = B = Al)

Fe: Akaganéite, $\beta\text{-FeOOH}$
 Schwertmannite, $Fe_8O_8(OH)_6(SO_4)$
Mn: Hollandite, $Ba_x(Mn^{IV}Mn^{III})_8O_{16}$, $x = 1$
 Cryptomelane, $K_x(Mn^{IV}Mn^{III})_8O_{16}$, $x = 1.3-1.5$
 Coronadite, $Pb_x(Mn^{IV}Mn^{III})_8O_{16}$, $x = 1.0-1.4$

Fe: Green rust, $Fe_4^{II}Fe_2^{III}(OH)_{12}(Cl,SO_4,CO_3)$

FIGURE 22.1 Structural schemes for oxide minerals in soils.

Mn: Chalcophanite, $ZnMn_3O_7 \cdot 3H_2O$
          Birnessite, (Na,Ca,Mn^{II}) $Mn_7O_4 \cdot 2.8H_2O$

Si: α-Cristobalite, SiO_2

Fe: Hematite, α-Fe_2O_3
Al: Corundum, α-Al_2O_3
Ti,Fe: Ilmenite, $FeTiO_3$

Ti: Anatase, TiO_2

Ti: Brookite, TiO_2

Fe: Magnetite, Fe_3O_4
          Maghemite, γ-Fe_2O_3
Mn: Hausmannite, Mn_3O_4
Ti,Fe: Titanomagnetite, $Fe_{3-x}Ti_xO_4$
          Titanomaghemite, $Fe_{2-x}Ti_xO_3$

Ti,Fe: Pseudobrookite, $Fe_2^{III}TiO_5$

Ti,Fe: Pseudorutile, $Fe_2^{III}Ti_3O_8(OH)_2$

Si: α-Quartz, SiO_2
